Northern Region R1-24-05 November 2023

Final Environmental Impact Statement for the Land Management Plan

Nez Perce-Clearwater National Forests

Final Environmental Impact Statement for 2023 Land Management Plan for the Nez Perce-Clearwater National Forests

Lead Agency:

United States Department of Agriculture (USDA)- Forest Service

Cooperating Agencies:

Idaho County, Idaho

Clearwater County, Idaho

State of Idaho

Government to Government Consulting Agency

Nez Perce Tribe

Responsible Official:

Cheryl Probert
Forest Supervisor
USDA Forest Service
Nez Perce-Clearwater National Forests
1008 Highway 64, Kamiah, Idaho 83536

For More Information Contact:

Zach Peterson
Public and Government Relations Staff Officer

208-935-4239 or zachary.peterson@usda.gov

Sara Daugherty
Forest Planner
1008 Highway 64, Kamiah, Idaho 83536
208-963-4206 or sara.daugherty@usda.gov

Abstract: This Final Environmental Impact Statement documents the analysis of the Preferred Alternative and four additional action alternatives developed for programmatic management of the four million acres of National Forest system lands administered by the Nez Perce-Clearwater National Forests. The purpose is to provide land management direction for the Nez Perce-Clearwater National Forests, combining the 1987 Nez Perce National Forests Land Management Plan and the 1987 Clearwater National Forest Land Management Plan into one plan for the Nez Perce-Clearwater National Forests, now managed as one administrative unit.

Commonly used acronyms

ARSC	Aquatic and Riparian Conservation Strategy
BA	Basal Area (square feet per acre)
CCF	Hundred Cubic Feet
CFR	Code of Federal Regulations
cfs	Cubic feet per second
CWN	Conservation Watershed Network
DBH	Diameter at Breast Height
DC	Desired Conditions
ESA	Endangered Species Act
FSH	Forest Service Handbook
FSM	Forest Service Manual
GA	Geographic Area
HUC	Hydrologic Unit Code
IRR	Idaho Roadless Rule
LCAS	Lynx Conservation and Assessment Strategy 2013
MA	Management Area
MBF	Thousand Board Feet
MMBF	Million Board Feet
MMCF	Million Cubic Feet
NEPA	National Environmental Policy Act 1970
NPCLW	Nez Perce-Clearwater National Forests
NRLMD	Northern Rockies Lynx Management Direction 2007
NRV	Natural Range of Variation
NWGC	National Wildfire Coordinating Group
PTSQ	Projected Timber Sale Quantity
PVT	Potential Vegetation Type
RMZ	Riparian Management Zone
RNA	Research Natural Area
ROS	Recreation Opportunity Spectrum
SIO	Scenic Integrity Objective
VCC	Vegetation Condition Class
WSR	Wild and Scenic River

Chapter 1. Purpose of and Need for Action

1.1 Introduction

The National Forest Management Act of 1976 (U.S. Department of Agriculture 1976a) requires the preparation of an integrated land management plan by an interdisciplinary team for each unit of the National Forest System. In May of 2012, the Forest Service began using new planning regulations (National Advisory Committee for Implementation of the National Forest System Land Management Planning 2018) to guide collaborative and science-based revision of land management plans that promote the ecological integrity of national forests while contributing to social and economic sustainability. Public involvement must be provided in preparing and revising land management plans (previously called 'forest plans').[1] Land management plans must provide for multiple use and sustained yield of products and services and include coordination of outdoor recreation, range, timber, watershed, wildlife and fish, and wilderness. The Land Management Plan does not authorize site-specific projects or activities; rather, it establishes broad direction to guide future project and activity decision making.

The Nez Perce and Clearwater National Forests were consolidated in 2013. The official name of the administratively combined forests is the Nez Perce-Clearwater National Forests. For the purposes of this document, the forests will be referred to as the Nez Perce-Clearwater. Prior to the official combination, each forest had its own Land Management Plan. Part of implementing the consolidation included a combined Land Management Plan effort, which includes the preparation of this Final Environmental Impact Statement.

The plan revision process began with preparation of an assessment that summarized the status and management of various resources on the Nez Perce-Clearwater. The assessment of the Nez Perce-Clearwater was published in June 2014. This assessment evaluated existing information about relevant ecological, economic, and social conditions, trends, and sustainability, and their relationship to the Land Management Plan within the context of the broader landscape. This information was used to identify any need for change in forest resources or in the management of those resources and as a basis for preparing the final Land Management Plan.

This Final Environmental Impact Statement documents a programmatic National Environmental Policy Act (NEPA) review. It discloses the broad environmental impacts and benefits of the proposed alternatives in contrast to analyses conducted for site-specific projects. This document describes, in general terms, the expected effects of management during the plan period but does not predict the site-specific effects of future speculative actions each time the standards and guidelines are implemented at the project level. Those site-specific effects would be disclosed in subsequent NEPA reviews during the implementation of individual projects.

1.2 Planning Area: The Nez Perce-Clearwater National Forests

The Nez Perce-Clearwater is in the heart of north-central Idaho in a seven-county region, comprising Idaho, Clearwater, Latah, Shoshone, Benewah, Lewis, and Nez Perce counties (figure 1).

[1] The terms "forest plan" and "land management plan" are used synonymously in this document.

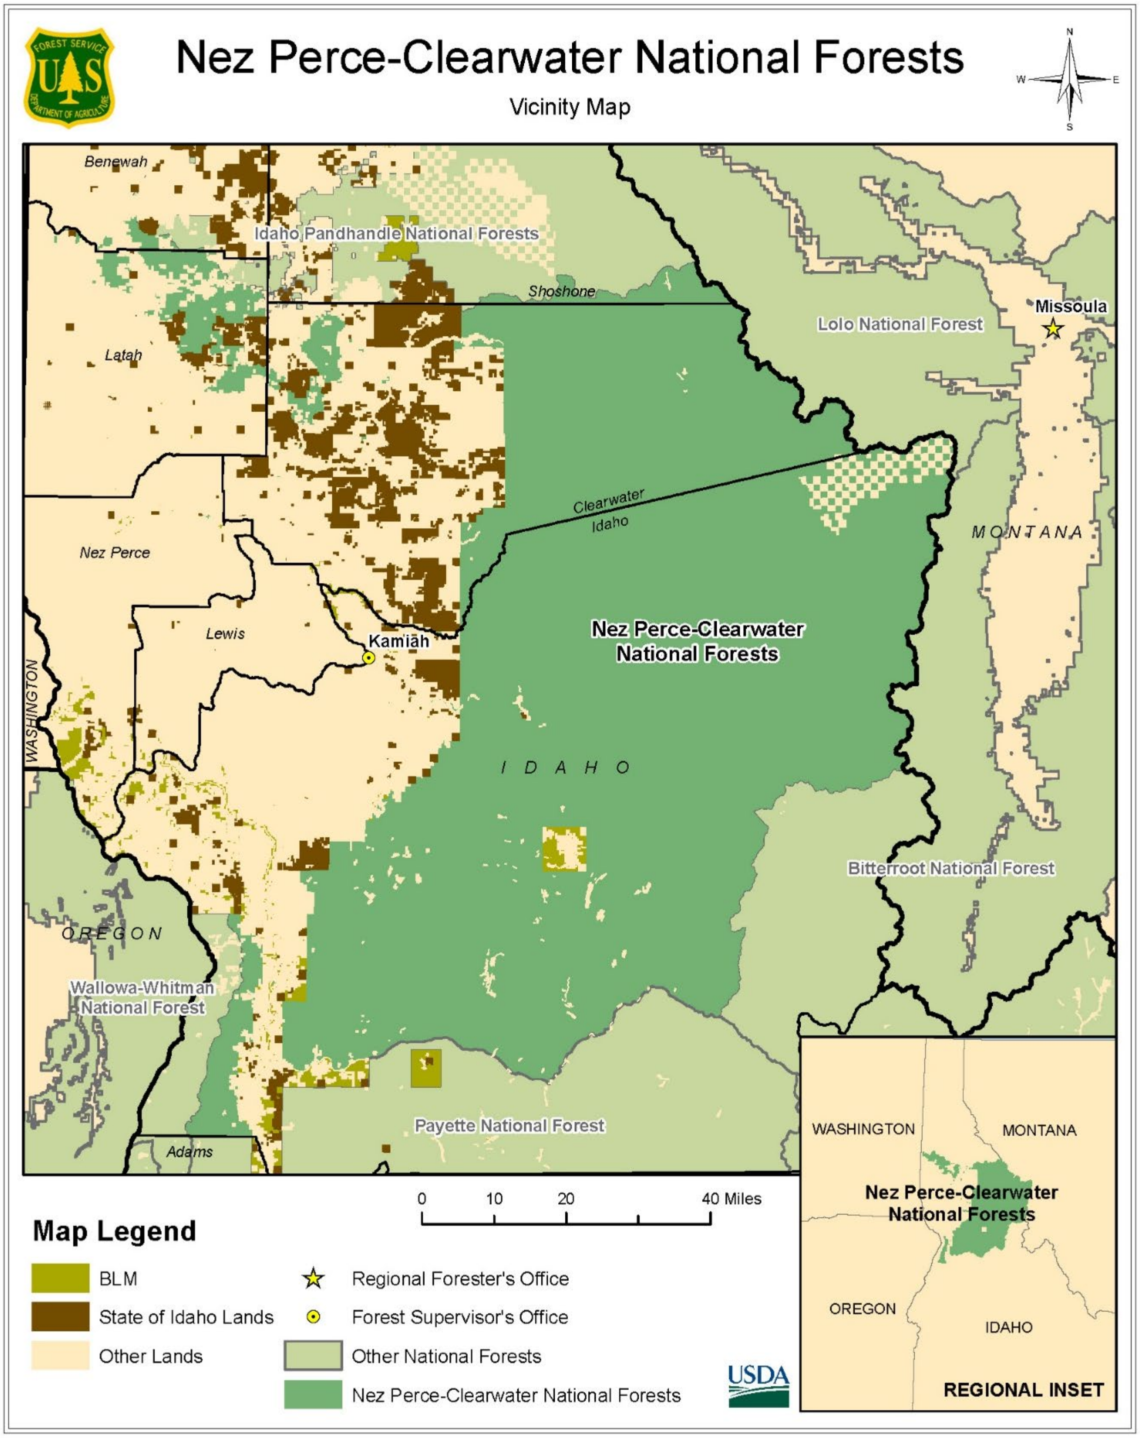

Figure 1. Map of the Nez Perce-Clearwater National Forests

The plan area encompasses six ranger districts: Palouse, North Fork, Lochsa and Powell, Moose Creek, Salmon River, and Red River. The Nez Perce-Clearwater is responsible for managing approximately four million acres across this landscape. The Clearwater River drains most of these acres within both forests and rugged mountain ranges, pristine rivers and streams, and extensive forested landscapes combine to create diverse ecosystems that provide spectacular recreational opportunities; substantial fish and wildlife habitat; and numerous forests, mineral, and range products.

The landscape of the Nez Perce-Clearwater is characterized by deep, rugged river canyons surrounded by either rolling hills or steep jagged mountains. Mixed conifer forests interspersed with small but distinctive open meadows, grasslands, and pockets of deciduous trees and shrubs comprise most of the vegetative cover. Rivers, lakes, and streams are often framed by lush riparian vegetation. Western redcedar, Western larch, western hemlock, Douglas-fir, grand fir, lodgepole pine, and Ponderosa pine are the dominant conifer species, which drape the canyon walls and stretch to the uplands. Historically, Western white pine and whitebark pine were found throughout the area. Disturbance in the form of wildland fire, landslides, and insect and disease are continually cycling through the landscape. These natural processes create a patchwork of openings with vegetation at all age classes found across the Nez Perce-Clearwater.

The rich heritage of the area is still visible. American Indian use of the area dates back for millennia and the Nez Perce-Clearwater has been the home of the Nez Perce Tribe for centuries. Early travelers used routes through the Bitterroot Mountains to explore the far reaches of the country. These events have been remembered through the designation of the Lolo Trail Historic Landmark corridor and other historic routes that bisect the Nez Perce-Clearwater. Historic mining towns, log cabins, Forest Service facilities, wagon roads, and fire lookouts dot the landscape, adding to the unique scenic character of the area.

1.2.1 Distinctive Roles and Contributions

The unique qualities of the Nez Perce-Clearwater and its ability to provide ecosystem services characterize the roles and contributions of the area. These roles and contributions provide the basis for management direction and the foundation for realistic and achievable desired conditions.

In addition to the role of providing common National Forest ecosystem services, such as clean air, clean water, nutrient cycling, and carbon sequestration, the Nez Perce-Clearwater plays a distinctive role in the local area, the region, and the nation by uniquely contributing diverse outdoor recreation opportunities; social and economic sustainability; cultural and heritage values, and ecological diversity.

Forest Service Planning

Forest Service planning takes place at different organizational levels and geographic scales. Planning occurs at three levels—national strategic planning, National Forest System unit planning, and project or activity planning. The Chief of the Forest Service is responsible for national planning, such as preparation of the Forest Service strategic plan that establishes goals, objectives, performance measures, and strategies for managing the national forests. National forest unit planning results in the development, amendment, or revision of a Land Management Plan, such as the Nez Perce-Clearwater Land Management Plan. The supervisor of the national forest is the responsible official for developing and approving a plan, plan amendment, or plan revision for lands under the responsibility of the supervisor. The forest supervisor or district ranger is the responsible official for project and activity planning (36 CFR 219.2).

National Strategic Planning

The U.S. Department of Agriculture (USDA) Forest Service Strategic Plan: Fiscal Years 2015–2020 contains four outcome-oriented goals for the Forest Service, each with strategic objectives. The strategic plan can be accessed online (www.fs.fed.us/strategicplan). The first two goals and related objectives are directly related to the current planning effort:

- Sustain our Nation's forests and grasslands
- Foster resilient, adaptive ecosystems to mitigate climate change
- Mitigate wildfire risk
- Conserve open space
- Deliver benefits to the public
- Provide abundant clean water
- Strengthen communities
- Connect people to the outdoors.

The Forest Service continues to use the results of the 2010 Resources Planning Act Assessment, a report on the status and projected future trends of the Nation's renewable resources on all forests and rangelands, as required by the 1974 Forest and Rangeland Renewable Resources Planning Act. The assessment includes analyses of forests, rangelands, wildlife and fish, biodiversity, water, outdoor recreation, wilderness, urban forests, and the effects of climate change on these resources. The assessment provides a snapshot of current United States forest and rangeland conditions (all ownerships), identifies drivers of change for natural resource conditions, and projects the effects of those drivers on resource conditions 50 years into the future. This assessment uses a set of future scenarios that influence the resource projections, allowing the exploration of a range of possible futures for renewable natural resources. Alternative future scenarios were used to analyze the effects of human and environmental influences on forests and rangelands, including population growth, domestic and global economic growth, land use change, and climate change.

In addition, the USDA strategic plan for fiscal years 2018 through 2022 has specific goals that also align with the 2012 Planning Rule, including (1) facilitate rural prosperity and economic development, and (2) ensure productive and sustainable use of National Forest System lands. The USDA strategic plan can be accessed on the USDA's website (www.usda.gov).

National Forest System Unit Planning

The National Forest Management Act of 1976 (Pub. L. 94-588) amended the Forest and Rangeland Renewable Resources Planning Act of 1974. The National Forest Management Act requires the preparation of an integrated Land Management Plan by an interdisciplinary team for each unit of the National Forest System (national forests and grasslands). The public must be involved in preparing and revising Land Management Plans, also called forest plans. Forest plans must provide for multiple use and sustained yield of products and services and include coordination of outdoor recreation, range, timber, watershed, fish, wildlife, and designated areas such as wilderness. The forest plan does not authorize site-specific prohibitions or activities; rather, it establishes overarching direction to guide future project and activity decision making.

The 2012 Planning Rule for Land Management Planning for the National Forest System sets forth process and content requirements to guide the development, amendment, and revision of Land Management Plans to maintain and restore National Forest System land and water ecosystems while providing for ecosystem services (the benefits people obtain from the National Forest System planning area) and multiple uses. The final planning directives, effective January 30, 2015, are the key agency guidance documents that direct implementation of the 2012 Planning Rule.

Outdoor Recreation

The diverse landscapes and stunning scenery of the Nez Perce-Clearwater provides extraordinary settings for recreational activities, such as camping, whitewater rafting, jet boating, trails for both motorized and non-motorized users, and fishing on the world-renown Selway, Salmon, Clearwater, and Lochsa Rivers.

Recreation opportunities also include wildlife-oriented recreation, such as hunting, wildlife watching, photography, and sport fishing. The Nez Perce-Clearwater provides crucial habitat for salmon, steelhead, and freshwater fish, which include nationally renowned blue-ribbon fishery streams, including Kelly Creek, the North Fork Clearwater River, and the Lochsa River.

The Nez Perce-Clearwater serves a unique national role providing vast, contiguous wildland areas, including the Selway-Bitterroot, Gospel-Hump, and Frank Church-River of No Return wilderness areas, with regional linkages to the Hells Canyon Wilderness and Idaho Roadless Rule areas, such as the Great Burn (Hoodoo) and Mallard-Larkins. Together these areas comprise the largest complex of unroaded lands in the lower 48 states.

Travel routes and corridors, such as the Northwest Passage Scenic Byway, also known as U.S. Highway 12; the Lolo Trail corridor, a National Historic Landmark; the Magruder Corridor; and the Elk City Wagon Road, trace the paths of the Nez Perce Tribe, Lewis and Clark, and early traders, providing recreation access and unique historical and cultural recreation experiences. The Nez Perce-Clearwater's road and trail systems provide a community backyard connection from the river valleys to the remote alpine elevations that are highly valued by residents and visitors. In addition, seven backcountry airstrips provide a distinct opportunity for access to the remote areas of the Nez Perce-Clearwater.

A network of trails and roads provide summer and winter access. Trail opportunities for both non-motorized and motorized users are plentiful in both the summer and the winter.

Social and Economic Sustainability

As the largest land jurisdiction in Idaho and Clearwater counties, the Nez Perce-Clearwater serves as a backdrop for the local area and plays a key role in supporting the social and economic sustainability of local communities, the State of Idaho, the Nez Perce Tribe, and the broader region. The productive forest lands continue to support traditional lifestyles and generational ties to the land; provide commodities, such as timber, grazing, and minerals, for regional industry; and sustain an outfitter and hunting guide recreation economy. The sport fisheries for spring and fall Chinook salmon, westslope cutthroat trout, steelhead trout, and kokanee and big game hunting opportunities for elk, black bear, moose, and big horn sheep are important components supporting the area's social and economic vitality.

The Nez Perce Tribe has reserved treaty rights, which entitle them to hunt, fish, gather, and graze livestock on the Nez Perce-Clearwater. Subsistence hunting, fishing, and gathering are both socially and economically critical to the Nez Perce people and are not viewed by them as recreation activities. The Nez Perce Tribe is involved in consultation regarding the management of the Nez Perce-Clearwater and staff from both organizations strive for a productive working relationship, particularly in efforts to support the recovery of anadromous fisheries. In addition to being culturally and socially important to the tribe, healthy salmon runs are an important economic component for both the tribe and local communities.

Cultural and Heritage Values

For millennia, the Nez Perce-Clearwater has been uniquely situated at the crossroads of several American Indian cultural areas, each possessing their own characteristic lifeways, languages, customs, and traditions. The river systems that bisect this topographically and culturally diverse region have helped create a unique archaeological and historical record on National Forest System land. The Salmon River is exceptional as the longest undammed river system in the contiguous United States. Through the centuries, the river was home to countless American Indians, Euro-American homesteaders, and miners, as well as Chinese sojourners. While thousands of archaeological sites now lie inundated under dams on the Columbia Plateau, the Salmon River flows free, and the archaeological record remains relatively intact.

The Nez Perce-Clearwater's rugged landscape required the development of ancient trail networks. The two most important were the Southern Nez Perce Trail and the Nez Perce National Historic Trail, which connected the Nez Perce homeland with buffalo country in Montana and the Northwestern plains and facilitated the dramatic 1877 flight of the Nez Perce from the U.S. Army. These mountain routes were also important to other Great Basin and Plateau American Indian groups, including the Coeur d'Alene, Shoshone, and Pend 'd Oreille and Flathead Salish tribes, who traveled and used the area for subsistence and trade and to maintain kinship ties and tribal alliances. Today, these American Indian groups and descendant communities, including the Nez Perce, retain an on-going and vibrant culture with unbroken ties to this region.

The history of the Nez Perce-Clearwater, especially that related to timber and mining, continues to influence local communities today. Mining began in the early 1860s around today's Elk City, Florence, and Pierce, Idaho. Together, these localities provided the political and financial impetus that culminated in Idaho statehood in 1890. Today, the ghost town of Florence is the oldest town site in Idaho on National Forest System land. The diverse landscape of the Nez Perce-Clearwater contains an abundance of agriculture, industrial, and domestic ruins and standing structures that document and enhance local history and are important to the identity of many rural communities within and near the Nez Perce-Clearwater boundaries.

Ecological Diversity

The Nez Perce-Clearwater is located directly in the path of ash dispersal from three major Pacific Rim volcanic eruptions – Glacier Peak, Mount Mazama, and Mount Saint Helens – depositing an ash cap as deep as 36 inches in some depressions. The resulting soil nutrient and water-holding capacity supports the Nez Perce-Clearwater's highly productive ecosystems.

The Nez Perce-Clearwater possesses a tremendous range and unusual diversity of habitats, from boreal and coastal elements in the north to extensive grasslands and pine forests in the south. The maritime influence of the Pacific Ocean also contributes to a unique coastal disjunct ecosystem with associated species uncommon to the Northern Rockies, such as the Coeur d'Alene and Idaho giant salamanders, deerfern, and Pacific dogwood. The local climatic transition caused by extreme terrain differences result in high floral diversity, including endemic species like the evergreen kittentail, Dasynotus, Idaho barren strawberry, spacious monkeyflower, the federally listed Spalding's catchfly, and four species of pine. The three major river systems, comprised of the Salmon, Clearwater, and Snake Rivers, and their accompanying tributaries, provide important aquatic and riparian habitat for many species, including bull trout, steelhead trout, westslope cutthroat trout, and Chinook salmon.

Additionally, many endemic gastropods are found in the major river systems, particularly in the Salmon River. The sheer number of endemic aquatic species within the planning area is notable and exemplary within the western United States. The Nez Perce-Clearwater's substantial spawning and rearing habitat for steelhead trout and Chinook salmon provides a large portion of the total returns of adult anadromous salmonids in the Snake and Columbia River basins.

In addition, the diverse vegetative communities on the Nez Perce-Clearwater provide terrestrial habitats that host several regionally unique native wildlife populations. This includes native lineages of fisher and bighorn sheep, as well as mountain quail, the white-headed woodpecker, and the harlequin duck. The extensive acreage of undeveloped lands, both on the Nez Perce-Clearwater and interconnected neighboring public lands, provide important habitat security and linkage for wide-ranging species, such as lynx, wolverine, and other carnivores. Historic large herds of elk are significant to the people of the area. Many economies within the planning area benefit greatly from the elk herds.

Plant and Animal Species

Bighorn Sheep

Rocky Mountain bighorn sheep historically occurred in northeastern Oregon, central Idaho, Montana, Wyoming, and northeastern Nevada. After a severe population decline in the early 1900s, bighorn remained in only a few isolated areas of their former habitat (Wisdom et al. 2000c, a). The current range represents an increase in occupied habitat since that time because of a combination of reintroductions and protection of remnant populations. Much of the historical range, however, is still unoccupied in the Salmon and Clearwater River basins and Idaho (Wisdom et al. 2000c, Idaho Department of Fish and Game 2005, Wisdom et al. 2000a).

Bighorn sheep prefer open habitats with short vegetation, both for high-quality forage (Wisdom et al. 2000c, a) and to maintain high visibility for predator avoidance. Additionally, cliffs, talus, and seasonal springs and seeps are important drivers of bighorn habitat. The location of cliffs and talus ultimately defines the distribution of bighorn sheep because such features are essential for escape cover and the secure rearing of young (Wisdom et al. 2000c, Bate and Wisdom 2004).

The primary reason the bighorn declined is due to their susceptibility to pneumonia after exposure to bacteria (*Pasteurella* spp.), viruses (Parainfluenza type-3), lungworm, and stress agents. Sources of these diseases are generally domestic sheep and goats. Major reductions or total extirpation of bighorn herds due to pneumonia outbreaks are well documented.

Bighorn sheep in the planning area have survived when other regional populations have been reduced or extirpated. This, coupled with the fact that domestic sheep grazing on the Nez Perce-Clearwater has been ongoing for centuries, make these populations of bighorn particularly interesting. In fact, individuals of this population have served as the source for other bighorn re-introductions around the west (Mack et al. 2017).

Bighorn sheep are a species of great cultural value to the Nez Perce Tribe. Additionally, they are an important game species historically and presently in Idaho.

Fisher

The Nez Perce-Clearwater National Forests and southern Idaho Panhandle National Forests are the primary areas that support fisher in the U.S. Forest Service Northern Region (Raley et al. 2012) (personal communication Sauder 2013, personal communication Schwartz 2013). The fisher is a forest-dependent species that evolved in the Northern Rocky Mountains in a complex landscape mosaic shaped by regularly occurring environmental influences on its preferred habitat, such as fire, tree disease, and wind-throw. Fishers are associated with areas of high cover and structural complexity in large tracts of mature and old-growth forests (Powell and Zielinski 1994, Sauder and Rachlow 2014, Schwartz et al. 2013). Other important site characteristics include the presence of nearby water, slope, elevation, and snow characteristics (U.S. Department of the Interior 2011a, Olson et al. 2014).

Anadromous Fish

The Nez Perce-Clearwater supports five fish species federally listed as threatened under the Endangered Species Act and one listed as endangered. Spring and summer Chinook salmon on the Nez Perce-Clearwater constitute nationally renowned fisheries of considerable local socioeconomic importance. Their cultural importance to the indigenous people of the area, particularly the Nez Perce Tribe, cannot be overstated. Snake River steelhead on and originating from the Nez Perce-Clearwater form a nationally renowned fishery of considerable socioeconomic importance, attracting anglers from all over the western United States and places beyond. Spawning and rearing habitat provided by rivers and streams on the Nez Perce-Clearwater are vital for both species within the context of the Snake River basin and for all stocks of Chinook salmon within the Columbia River basin. Bull trout exist within all subbasins throughout the Nez Perce-Clearwater, including the North Fork Clearwater subbasin. Fall Chinook salmon occur within the Salmon River, and sockeye salmon use the Salmon River as a migration corridor to headwater reaches of the Salmon basin.

Endemic gastropods

The plan area supports high gastropod diversity, including slugs and snails. In fact, approximately 68 species of gastropods are known to occur in the plan area, which is the result of the Northern Rocky Mountain refugium (Stagliano et al. 2007) (Brunsfeld et al. 2001). This area occurs along the Idaho and Montana border and was neither covered by northern ice sheets during glaciation periods nor paved with lava from the south and west (Stagliano et al. 2007). Many species of gastropods in the plan area are regional endemic species limited to northern Idaho, western Montana, southern British Columbia, and eastern Washington. Others are Idaho endemics limited in many cases to Idaho while some are local endemics with distributions limited to parts of the Nez Perce-Clearwater and some lands just outside the plan area. The Selway forestsnail (*Allogona lombardii*), the Mission Creek Oregonian (*Cryptomastix magnidentata*), and the Nimapuna disc (*Anguispira nimapuna*) are some examples of local endemic gastropods.

Similarly, the lower Salmon River canyon has exceptional landsnail diversity, which has been recognized by scientists since the 1860s (Frest and Johannes 1995) (Frest and Johannes 1997). Several species and sub-species of landsnail species are local endemics limited to the lower Salmon River canyon. Some of them are only known from small or scattered areas within the lower Salmon River canyon. Most of these species occur outside of the plan area boundaries at lower elevations but some taxa have been observed on Nez Perce-Clearwater.

Elk

Historically, elk herds were scattered, and numbers were low in the planning area. Few elk were found along the Clearwater River by Lewis and Clark in the early 1800s, probably due in part to the dense, unbroken canopy of forest that covered the area. Wildfires burned over vast expanses near the beginning of the twentieth century, creating vast shrub-fields that provided abundant forage areas for elk. Elk numbers subsequently increased and then peaked around 1950. Elk herds declined into the 1970s, partially due to the maturation of the shrub-fields and ensuing decline in forage availability, and logging and road-building activity increased elk vulnerability to hunters under liberal hunting seasons and the loss of some major winter ranges due primarily due to invasive species (Wakkinen, Hickey, et al. 2017).

Elk are a high profile culturally important species, both historically and currently, and one of high economic value in the area. Much local collaboration has occurred with the primary goal of increasing elk herds. The Nez Perce-Clearwater is considered essential in providing habitat for elk.

Harlequin Duck

Harlequin ducks are medium sized ducks that prefer turbulent, highly oxygenated waters. They breed in fast moving mountain streams and prefer rivers with closed canopies for breeding. On the Nez Perce-Clearwater, populations are routinely monitored on the Lochsa River and its major tributaries, including North Fork Spruce Creek. The Lochsa River has the highest number of breeding pairs of harlequins in the State of Idaho, according to the 2017 Idaho State Wildlife Action Plan (Idaho Department of Fish and Game 2017b). Many observations are documented to occur on tributaries of the North Fork Clearwater and Selway Rivers (Idaho Species Diversity Database[2]).

Harlequin duck migrate and winter on rocky coastlines. Harlequin ducks face many of the same threats other migratory birds face and their populations have diminished greatly over time. The breeding habitats on the Nez Perce-Clearwater are some of the best breeding habitats in Idaho and in the continental United States.

Mountain Quail

Mountain quail populations on the Nez Perce-Clearwater are remnants of once larger populations in Idaho and Oregon. Until the 1950s, mountain quail populations were abundant in western Idaho. They were found from the southwestern deserts north to the area along the lower Snake, Salmon, and Clearwater Rivers. Now they are found in only a few places, mostly along the Salmon River. They live in steep rugged terrain and can survive along dry slopes. The reasons for their decline are unknown. Mountain quail, as their name suggests, are usually found at higher elevations, unlike the more common California or valley quail. Mountain quail are quite unique. They are Idaho's largest quail species and the only North American quail that exhibits locally migratory behavior. They move up and down along riparian zones changing elevation depending on snow conditions, food availability, and other factors.

Whitebark Pine

Whitebark pine (*Pinus albicaulis*), a federally listed tree species, is found at higher elevations on the Nez Perce-Clearwater. Whitebark pine is native to subalpine and timberline zones. In northern Idaho, whitebark pine is a seral component of subalpine fir communities and dominates the highest peaks and ridges of greater than approximately 6,000 feet. Understory cover is typically discontinuous on these high-elevation sites. Engelmann spruce, Rocky Mountain lodgepole pine, and Rocky Mountain Douglas-fir may associate with whitebark pine, especially on mid-elevation sites. Whitebark pine is a fire adapted species, reseeding quickly following fire with assistance from the Clark's nutcracker. Due to white pine blister rust, a fungus that causes about 96 percent mortality once infected, mountain pine beetle, fire suppression and climate change, whitebark pine is in decline across its native range.

Project and Activity Planning Consistency and Transition to the Revised Plan

As required by National Forest Management Act and the Planning Rule, subject to valid existing or statutory rights, all projects and activities authorized by the Forest Service after approval of this plan must be consistent with the applicable plan components (16 U.S.C. 1604(i)) as described at 36 CFR 219.15. Projects and activities approved before the revised plan's approval are not required to meet the direction of the revised plan and will remain consistent with the direction in the 1986 and 1987 forest plans, as amended.

All project or activity approval documents, made after the effective date of the plan, will describe how the project or activity is consistent with the applicable components of the forest plan. When a proposed project or activity would not be consistent with the applicable plan components, the responsible official shall take one of the following steps, subject to valid existing rights:

1. Modify the proposed project or activity to make it consistent with the applicable plan components;
2. Reject the proposal or terminate the project or activity;
3. Amend the plan so that the project or activity will be consistent with the plan as amended;
4. Amend the plan contemporaneously with the approval of the project or activity so that the project or activity will be consistent with the plan as amended. This amendment may be limited to apply only to the project or activity.

Resource plans (for example, travel management plans) developed by the national forest that apply to the resources or land areas within the planning area must be consistent with the plan components. Resource plans developed before this plan decision will be evaluated for consistency with the plan and updated, if necessary, through site-specific National Environmental Policy Act decision making.

Authorizations for occupancy and use made before this plan approval may proceed unchanged until time of reauthorization. At time of reauthorization, all permits, contracts, and other authorizing instruments must be made consistent with the Land Management Plan, subject to valid existing or statutory rights, as provided at 36 CFR 219.15(d).

1.3 Background to Forest Land Management Planning

1.3.1 Forest Plan Revision: Land Management Planning

The National Forest Management Act requires all national forests to develop plans that direct resource management activities. These plans must be revised when conditions have changed significantly or around a ten- to fifteen-year cycle.

The existing Forest Plans for the Nez Perce and Clearwater National Forests were completed in 1987 and have been amended many times. The two Forests were administratively combined in 2013, and the Idaho Roadless Rule made management decisions that affected approximately 1.5 million acres of the Nez Perce-Clearwater. Revised Forest Service policies, congressional direction, court decisions, new or updated conservation agreements and recovery plans, and new scientific findings have all highlighted that the current plans are outdated and need to be revised.

To respond to these challenges the Nez Perce-Clearwater is currently in the process of revising the forest plans. The new, combined Land Management Plan will incorporate changes in the natural environment, will include new scientific understandings and social trends, and will satisfy regulatory requirements.

Eight primary decisions are made in Land Management Plans:

1. Forestwide components to provide for integrated social, economic, and ecological sustainability and ecosystem integrity and diversity while providing for ecosystem services and multiple uses. Components must be within Forest Service authority and consistent with the inherent capability of the plan area (36 CFR 219.7 and CFR 219.8–219.10).
2. Recommendations to Congress (if any) for lands suitable for inclusion in the National Wilderness Preservation System and/or rivers eligible for inclusion in the National Wild and Scenic Rivers System (36 CFR 219.7(2)(v) and (vi)).
3. Identification or recommendation (if any) of other designated areas (36 CFR 219.7 (c)(2)(vii).
4. Identification of suitability of areas for the appropriate integration of resource management and uses, including lands suited and not suited for timber production (36 CFR 219.7(c)(2)(vii) and 219.11).
5. Identification of the maximum quantity of timber that may be removed from the plan area (36 CFR 219.7 and 219.11 (d)(6)).
6. Identification of geographic or management area specific components (36 CFR 219.7 (c)(3)(d).
7. Identification of watersheds that are a priority for maintenance or restoration (36 CFR 219.7 (c)(3)(e)(3)(f).
8. Plan monitoring program (36 CFR 219.7 (c)(2)(x) and 219.12).

Many other laws and regulations apply to the management of the national forests, including, but not limited to, the National Trails Act, the Clean Air Act, the Clean Water Act, and the Endangered Species Act. These laws are generally not repeated or referenced in the language of the Land Management Plan unless there is an issue that merits a reference to the direction of the law.

Additional direction for managing National Forest System lands comes from a variety of sources, including Executive Orders, the Code of Federal Regulations, and the Forest Service directive system, which consists of the Forest Service Manual and the Forest Service Handbook. This direction does not need to be restated in the Land Management Plan and will not be found in the following sections.

1.3.2 Nature of the Decisions Made in a Land Management Plan

Land Management Plans (previously and synonymously called "Forest Plans") are strategic in nature, making general decisions that are often referred to as programmatic decisions. They provide the framework for integrated resource management and guidance for subsequent project and activity decision making on the Nez Perce-Clearwater.

The revised plan will describe desired ecological, social, and economic conditions of the Nez Perce-Clearwater and provide plan component direction that will focus management activities towards maintaining or achieving those conditions over time. The proposed plan components are designed to provide for the maintenance and restoration, where needed, of the ecological integrity of terrestrial and aquatic ecosystems and watersheds; to guide the Nez Perce-Clearwater's contribution to social and economic sustainability; and to meet the Forest Service's responsibility to American Indian tribes in relation to trust responsibilities and treaty resources.

Historically, many forest communities developed strong natural-resource-based economies in the mining, logging, agricultural, and grazing industries. Over time, other values have become increasingly important, such as protecting water quality and quantity, providing recreational settings that support tourism, and providing for functioning and intact ecosystems. Forest planning today seeks to balance these public values and expectations. When making decisions for the revised plan, the potential ecological and biological impacts will be examined, as well as the economic and social impacts to the Nez Perce Tribe, local counties, the broader regional level, and the nation.

1.3.3 Life of the Plan

The National Forest Management Act of 1976, Section 6 Part 5, modified the Forest and Rangeland Renewable Resources Planning Act of 1974 to require Land Management Plans and states that plans shall "be revised from time to time when the secretary finds conditions in a unit have significantly changed, but at least every fifteen years." Based on experience nationwide, however, plans remain in effect until such time they are revised by a new plan, which may be longer than fifteen years between revisions. The first forest plans on the Nez Perce and Clearwater National Forests have been in effect since 1987 and will continue to be in effect until a Record of Decision is signed on a revised plan, estimated to be 34 years since the forest plans originated. As such, the life of the plan throughout this environmental impact statement will be used to mean the time from the signing of a Record of Decision on this plan through signing a Record of Decision on future Land Management Plans. The timeframe is assumed to be 20 to 30 years, despite the regulatory definition of not to exceed fifteen years. When "the life of the plan" is used in plan components or analysis, it is assumed that the component or analysis will be based on implementation over 20 to 30 years.

1.4 Purpose and Need for Change

In developing a proposed plan revision, the responsible official "shall review relevant information from the assessment and monitoring to identify a preliminary need to change the existing plan and to inform the development of plan components and other plan content" (36 CFR 219.7 (c)(2)(i)).

The need to change a plan should be predicated on the status of key ecosystem characteristics, the needs and opportunities for restoration or maintenance of these characteristics, and the potential for plan components to promote ecological integrity within the terrestrial, riparian, and aquatic ecosystems relevant to the plan area. The assessment of ecosystem integrity and status of at-risk species in the plan area should be reviewed to identify and evaluate opportunities for the plan area to maintain ecological sustainability and the diversity of plant and animal communities.

Similarly, the responsible official's identification of the need to change the plan should identify opportunities for the plan area to contribute to the social and economic sustainability of the plan area and affected communities.

The purpose is to revise the 1987 Land Management Plans for the Clearwater and Nez Perce Forests into a single revised Land Management Plan under the 2012 Planning Rule.

1.4.1 Administrative Consolidation and Age of Current Plans

In February 2013, a five-year effort to consolidate leadership and programs across the Nez Perce and Clearwater National Forests culminated in a decision to combine the forests into a single administrative unit called the Nez Perce-Clearwater National Forests. Forest Service planners analyzed both the Nez Perce and Clearwater National Forests existing plans in their entirety and identified areas where adjustments are necessary. The two individual 1987 Forest Plans provide different management strategies for some resources, such as recommended wilderness areas or elk habitat. Implementation monitoring of the existing plans have identified management concerns. Additionally, the 2014 Nez Perce-Clearwater National Forests' Assessment[3] and input from collaborative public outreach has identified new information that contributes to the need for change.

The National Forest Management Act includes a provision to "revise forest plans from time to time when the Secretary finds conditions in a unit have significantly changed, but at least every fifteen years" (16 U.S.C. 1604(f)(5)(A)). The 1987 Forest Plans were developed under planning regulations completed in 1979 and amended in 1982 Planning Rule. Since that time, much has changed regarding our understanding of land management planning, including improved understanding of science and sustainability, as well as a better understanding of the values and benefits public lands provide citizens. The current plans limit the pace and scale of restoration and are slow to respond to the challenges of changing conditions, such as climate change or recreation demand. In May of 2012, the Forest Service began implementation of new planning regulations, titled the 2012 Planning Rule (36 CFR 219), to guide collaborative and science-based revision of Land Management Plans that promote the ecological integrity of national forests while considering social and economic sustainability.

Need for Change

There is a need to revise the two 1987 Forest Plans under the provisions of the 2012 planning regulations to provide the combined forests consistent, adaptable management guidance in consideration of best available scientific information while continuing to provide a range of social, economic, and ecological benefits for the present and into the future.

1.4.2 Integrated Restoration

Current forest plan monitoring, the 2014 Assessment, the 2014 Climate Change Vulnerability Assessment, and the 2011 Watershed Condition Assessment identify integrated restoration needs across the Nez Perce-Clearwater to address forest health, including resiliency to stressors, such as insects and disease, drought, and climate change; wildfire risk; aquatic and terrestrial wildlife habitat; invasive species; soil productivity and function; and road management. In February 2012, then Secretary Tom Vilsack released the Increasing the Pace of Restoration and Job Creation on Our National Forests report. It describes the need to increase the pace and scale of restoration of the nation's forests to improve both the ecological health of our forest ecosystems and the economic health of forest-dependent communities. The report outlines management actions that land managers can utilize to step up the pace and scale of restoration activities on the ground.

Need for Change

There is a need to revise the 1987 Forest Plans to emphasize integrated restoration of terrestrial and aquatic resources to restore vegetation composition, structure, and landscape patterns; reduce fuel loading; and improve watershed conditions to support wildlife and other resource values while contributing to the social and economic sustainability of local and regional communities.

[3] https://www.fs.usda.gov/detail/nezperceclearwater/landmanagement/planning/?cid=stelprdb5396919

1.4.3 Ecological, Social and Economic Sustainability

The 2012 Planning Rule directs the Forest Service to manage National Forests for ecological, social, and economic sustainability. In addition, the rule considers the three as having equal importance in revising Land Management Plans.

Need for Change

There is a need to revise the 1987 Forest Plans to provide for ecological, social, and economic sustainability in an integrated manner. Additionally, the plans need to be revised to better consider multiple uses and ecosystem services desired by local, regional, and national publics.

1.4.4 Updates Related to Other Law, Regulation, or Policy

In addition to updated planning regulations since development of the 1987 Plans, laws and other regulations have changed and additional species have been listed as threatened or endangered under the Endangered Species Act.

Need for Change

There is a need to revise the 1987 Forest Plans based on best available scientific information to update direction from the Inland Native Fish Strategy (INFISH) and Pacific Anadromous Fish Strategy (PACFISH) with forest-specific aquatic conservation strategies. There is a need to update lynx habitat boundaries from the 2007 Northern Rockies Lynx Management Direction. In addition, there is a need to incorporate direction established in the Idaho Roadless Rule.

1.4.5 State and Local Land Management Plans

There is a need coordinate land management planning with the planning efforts of federally recognized Indian Tribes, other Federal agencies, and State and local governments (2012 Planning Rule 36 CFR §219.4(b)). Development of the proposed Land Management Plan considered local and state plans. Chapter 3 provides a summary of how local plans were incorporated into the planning process and any items that could not be incorporated into an alternative.

Plans considered include:

Nez Perce Tribe

- Idaho Department of Parks and Recreation Strategic Plan (https://parksandrecreation.idaho.gov/about-parks-recreation/)

1.4.6 Best Available Scientific Information

There is a need to incorporate new information and science into plan guidance. Inventory information about forest land and water resources is more comprehensive than what was available in 1987, because of continued updates and new data management tools. The Forest Service now has geographic information system (GIS) technology, which greatly enhances assessment, analysis, and monitoring. Research and monitoring have increased our knowledge of the physical, biological, and social processes occurring on the Nez Perce-Clearwater during the last quarter of a century. Using science in planning provides the responsible official with the knowledge, methods, and resource expertise needed to make an informed decision. In addition, the Nez Perce Tribe holds unique traditional ecological and cultural knowledge of the area. To ensure that the revised plan helps contribute to sustainable stewardship of the nation's forests, the Nez Perce-Clearwater has used the best available scientific information to inform the 2014 Assessment and the development of the proposed plan components.

Specialists used multiple resources that included peer-reviewed and technical literature; databases and data management systems; modeling tools and approaches; information obtained via participation and attendance at scientific conferences; local information, workshops, and collaborations; and information received during public participation periods for related planning activities. Resource specialists considered what is most accurate, reliable, and relevant in their use of the best available scientific information. The citations in Chapter 3 (and corresponding Literature Cited), as well as additional data stored in the project record, serve as the Nez Perce-Clearwater's initial list of best available scientific information. A final determination of best available scientific information will be made with the Record of Decision.

1.5 Scoping

The Nez Perce-Clearwater is proposing to revise the current Land Management Plans. Scoping was done with the release of the July 2014 proposed action and Notice of Intent in the Federal Register (79 Federal Register 41252 document number 2014-16534). The proposed action document included preliminary identification of forestwide and management area desired conditions, objectives, standards, guidelines, and the suitability of lands for specific multiple uses, including those lands suitable for timber production. The proposed action included preliminary identification of the long-term sustained yield and planned sale quantity. It included a description of the plan area's distinctive roles and contributions within the broader landscape; the preliminary identification of priority restoration watersheds; and proposed and possible actions that may occur on the plan area over the life of the plan. The 2014 proposed action yielded 13,800 comments. From those comments, issues were identified (see Section 1.7).

Modifications of the 2014 proposed action led to the release of the 2017 Framework for Alternative Development. This document explicitly stated it was not an alternative, but rather a set of theoretical plan components that could be used to develop alternatives. That document was considered as an alternative but will not be analyzed in detail. Some portions of the Framework for Alternative Development moved forward into one or more action alternatives to be analyzed based on robust collaboration during alternative development while other portions did not move forward at all.

1.6 Decision Framework

Given the need for change, the deciding official reviews the action alternatives, the No Action Alternative, the Preferred Alternative, and the environmental consequences to make the following decisions:

- Forestwide components to provide for integrated social, economic, and ecological sustainability and ecosystem integrity and diversity while providing for ecosystem services and multiple uses. Components must be within Forest Service authority and consistent with the inherent capability of the plan area (36 CFR 219.7 and CFR 219.8–219.10).
- Identification of geographic or management area specific components (36 CFR 219.7(d)).
- The plan's distinctive roles and contributions within the broader landscape.
- Identification of suitability of areas for the appropriate integration of resource management and uses, including lands suited and not suited for timber production (36 CFR 219.7(c)(2)(vii) and 219.11).
- Identification of the maximum quantity of timber that may be removed from the plan area (36 CFR 219.7(c)(2)(ix) and 219.11(d)(6)).
- Identification of watersheds that are a priority for maintenance or restoration (36 CFR 219.7(f)(i)).
- Recommendations to Congress (if any) for lands suitable for inclusion in the National Wilderness Preservation System and/or rivers eligible for inclusion in the National Wild and Scenic Rivers System (36 CFR 219.7(c)(2)(v) and (vi)).
- Identification or recommendation (if any) of other designated areas (36 CFR 219.7 (c)(2)(vii).
- Plan monitoring program (36 CFR 219.7(c)(2)(x) and 219.12).

The responsible official for the Land Management Plan is the Forest Supervisor. After reviewing the results of the analysis evaluated in the Final Environmental Impact Statement, the responsible official will issue a draft record of decision, in accordance with agency decision making procedures (40 CFR § 1505.2) that will:

- disclose the decision (identifying the selected alternative) and reasons for the decision.
- discuss how public comments and issues were considered in the decision, and
- discuss how all alternatives were considered in reaching the decision, specifying which one is the environmentally preferable alternative (defined in 36 CFR § 220.3).

The Land Management Plan provides a set of integrated plan direction for managing the Nez Perce-Clearwater for the next 10 to 15 years. However, even after approval of the plan, project level environmental analysis will still need to be completed for specific proposals to implement the direction in the Land Management Plan.

Land management plans do not make budget decisions. Should Congress emphasize specific programs by appropriation, a redistribution of priorities would follow, regardless of the alternative implemented.

1.7 Public Involvement and Collaboration

The Nez Perce-Clearwater began public participation activities in 2012 and facilitated numerous public and interagency meetings to bring together information for the Nez Perce-Clearwater to consider in preparing the assessment, developing the proposed action, and developing alternatives to the proposed action. There were 22 rounds of public meetings between 2012 and 2014 to develop the 2014 Proposed Action. The first meeting was a summit to introduce the concepts of forest plan revision to the public. The next meetings discussed the Need to Change, the Desired Conditions, and Forest Resource Management, including wilderness and timber suitability and other plan components. Public input was compiled at each meeting, as well as throughout the process. The dialogue and recommendations from this public involvement process were used to help develop the proposed action.

In addition to postal mail and email, public meeting information was announced via the forest plan revision website.[4] The website also included a means for public comment using electronic or printed comment forms or submitting comments via an electronic database and posted meeting results and other information. Updates were posted periodically.

The notice of intent for the proposed action to prepare an environmental impact statement was published in the Federal Register on July 14, 2014. The notice of intent asked for public comment on the proposal for a 60-day period, which was extended to 120 days based on public requests. The Nez Perce-Clearwater held five public meetings to provide opportunities to better understand the proposed action so that meaningful public comments could be provided by the end of the scoping period. Using the comments from the public, other agencies, tribes, and organizations, the Nez Perce-Clearwater interdisciplinary team developed a list of issues to address through changes to the proposed action, development of alternatives, or in analysis of impacts of the proposed action. A corrected notice of intent was published on September 5, 2019, to correct the anticipated dates of

[4] https://www.fs.usda.gov/detail/nezperceclearwater/landmanagement/planning/?cid=stelprdb5447338

availability of the Draft Environmental Impact Statement from 2015 to 2019 based on changes to the timeline.

Since the scoping period, public involvement has been ongoing. Stakeholders have been defined as any individual, organization, government, or tribe that is interested in our planning process. The forest plan revision team met with thousands of individuals from hundreds of organizations since 2012. Following the scoping period, the team continued to meet with any and every organization that invited the team to meet with them. This included attendance at well over 100 meetings between 2014 and the release of the Draft Environmental Impact Statement. The Nez Perce-Clearwater convened meetings on several occasions, including a meeting in May 2015 to update the public on what has happened since scoping, a webinar in December 2017 to prepare the public for alternative development, a meeting in January 2018 to solicit input on alternatives over three days in two locations, and another meeting in the summer of 2018 to share the alternatives being analyzed with the public over six meetings across the Nez Perce-Clearwater. Additionally, in 2018, County Commissions were briefed in public county commission meetings in the counties of Idaho, Clearwater, Latah, Lewis, Nez Perce, Benewah, and Shoshone in Idaho and the counties of Ravalli, Superior, and Missoula in Montana.

Comments have been accepted at any time during the process and that acceptance will continue throughout the process. These comments have helped the interdisciplinary team develop plan components and alternatives, conduct analysis, determine the best available scientific information, conduct wilderness evaluations, create wild and scenic suitability reports, and develop a monitoring plan. Comments have also been used by the Regional Office in development of the Species of Conservation Concern (SCC) list.

Collaboration with groups terming themselves as such has also provided the Nez Perce-Clearwater with information that is used by the Nez Perce-Clearwater the same as other comments. The Nez Perce-Clearwater attends their meetings at their invite and does not give any decision-making authority to these collaborative groups. However, groups of people with diverse thoughts and needs working to solve problems working towards consensus on issues is taken very seriously and input of this sort is highly valued by the Forest Service, whether it comes from an organized collaborative or from elsewhere. The interdisciplinary team has meet with the following collaborative groups since 2012:

- Forest Plan Collaborative 2012-2014, U.S. Forest Service convened
- Clearwater Basin Collaborative (CBC) 2014-current, at their invitation
- Efficiency in Public Collaborative (EPC) 2019-2020

The State of Idaho has been involved with forest planning since 2012. Various state agencies have been present at public meetings, met with the interdisciplinary team, provided information and data, and assisted in the development of plan components.

State agencies, offices, and commissions that have been involved include:

- Idaho State Department of Agriculture
- Idaho Department of Environmental Quality
- Idaho Department of Fish and Game
- Idaho State Historic Preservation Office

- Idaho Department of Lands
- Idaho Department of Parks and Recreation
- Idaho Department of Water Resources
- Idaho Geological Survey
- Idaho Governor's Office of Species Conservation.
- Idaho Governor's Idaho Roadless Commission
- Idaho Governor's Lewis and Clark Trail Commission

Four agencies or governments have signed a cooperating agency agreement for plan revision with the Forest Service. These cooperating agencies participate in the development of the Land Management Plan and Final Environmental Impact Statement with regards to their areas of specialized expertise. Cooperating agency participation in the forest plan revision is not an endorsement of the Land Management Plan nor does cooperating agency status limit their ability to participate during the public involvement process. Cooperating agencies include:

- Idaho County
- Clearwater County
- State of Idaho by and through the Idaho Governor's Office of Species Conservation

The Forest Service has consulted with the Nez Perce Tribe through the life of the revision of the Land Management Plan. The Tribe has been influential in the preparation of both the Draft and Final Environmental Impact Statements. Staff to staff meetings between the Tribe and the Forest Service began in 2012 are ongoing. Forest Leadership has also met with the Nez Perce Tribal Executive Committee to provide updates and incorporate important components to the Land Management Plan.

Following the release of the Draft Environmental Impact Statement, the publication of the Federal Register Notice on December 20, 2019, initiated a formal 90-day comment period. The comment period was extended for 30 days, concluding on April 20, 2020, for a total comment period duration of 120 days. Public meetings were held in Kamiah, Grangeville, Orofino, Elk City, Lowell, Coeur d'Alene, Lewiston, Moscow, Riggins, McCall, and Boise in Idaho and Superior, Missoula, and Hamilton in Montana. Comments were accepted through the Forest Plan Revision commenting site, by e-mail, and by written mailed or hand delivered comment.

During the formal comment period, 20,837 comments were received in total. 1,329 unique comment letters were received. Within these letters, 4,134 individual substantive comments were identified. The substantive comments were grouped into 133 concern categories with approximately 400 concern statements were developed from these substantive comments. See Appendix M for additional information and a response to the concern statements.

As part of the public involvement process, the agency has made available the documents listed on the Nez Perce-Clearwater webpage.[5]

[5] Nez Perce-Clearwater Forest Plan Revision webpage: https://www.fs.usda.gov/detail/nezperceclearwater/landmanagement/planning/?cid=stelprdb5447338

1.8 Issues

The Nez Perce-Clearwater separated the issues into two groups: significant and non-significant issues. Significant issues were defined as those directly or indirectly caused by implementing the proposed action. Non-significant issues were identified as those: 1) outside the scope of the proposed action; 2) already decided by law, regulation, Land Management Plan, or other higher-level decision; 3) irrelevant to the decision to be made; or 4) conjectural and not supported by scientific or factual evidence. The Council on Environmental Quality National Environmental Policy Act regulations explain this delineation in Section 1501.7 as "…identify and eliminate from detailed study the issues which are not significant, or which have been covered by prior environmental review (Sec. 1506.3) …" A list of non-significant issues and reasons regarding their categorization as non-significant may be found in the project record.

1.8.1 Significant Issues

The Nez Perce-Clearwater identified four significant issues during scoping based on the scoping document titled "Proposed Action."[6]

Recommended Wilderness and Wild and Scenic Rivers

Issue 1: The Proposed Action may not adequately apportion recommended wilderness areas across the Nez Perce-Clearwater. The proposed action may not adequately apportion suitable Wild and Scenic River segments across the Nez Perce-Clearwater.

Background: The Nez Perce- Clearwater contains some of the wildest lands in the United States. Parts of three wilderness areas are found on the Nez Perce-Clearwater. The Nez Perce-Clearwater is also home to wild rivers, including the Middle Fork Clearwater River and Salmon Rivers, which were among the first to be designated in the original Wild and Scenic Rivers Act. Yet many more acres of wild country and many more miles of wild rivers are found on the Nez Perce-Clearwater. The Planning Rule directs the Nez Perce-Clearwater to evaluate areas to determine if they should be recommended for wilderness and look at rivers to determine if they are eligible and suitable for inclusion in the Wild and Scenic Rivers system.

Recommended wilderness and wild and scenic rivers are a polarizing topic amongst the public. While nearly all acknowledge they appreciate wild lands and wild and free rivers, there is no agreement as to how best to manage those lands. During collaborative efforts and based on comments received, many expressed concerns that additional recommended wilderness areas were not warranted. Some felt the current designated wilderness areas are already the best possible wilderness areas. Others stated that by percentage, the Nez Perce-Clearwater has a very high amount of designated wilderness areas compared to other national forests, regions, states. Many were concerned with the loss of recreational opportunities, including motorized, over-the-snow, and mechanized uses, that may come with additional recommended wilderness areas. Similarly, citizens and elected officials are concerned with the negative economic impact that may be realized by counties by recommending wilderness areas. Also mentioned was the perspective that the Idaho Roadless Rule (IRR) has successfully maintained many of the wilderness characteristics of these areas. Alternatively, many commented that the Nez Perce-Clearwater has some of the largest

[6] The 2014 Proposed Action was a scoping document originally intended to be an alternative analyzed in the Draft Environmental Impact Statement. However, based on internal and external comments, that alternative will not be analyzed in detail in the Environmental Impact Statement (EIS). The issue statements from the Proposed Action helped to form all action alternatives in the EIS. References to the proposed action refer to the 2014 scoping document, not a proposed or preferred alternative in the Draft Environmental Impact Statement.

remaining roadless expanses in the United States and that those should be protected by recommending them for a wilderness area designation. Many felt that the Idaho Roadless Rule does not adequately protect the Idaho Roadless Areas due to the allowance of motorized travel within them. A few wanted all or most all Idaho Roadless Areas to be recommended as wilderness areas. Many wanted many roadless areas, but not all, to be recommended. Others wanted specific areas to be recommended for a variety of ecological and social reasons.

The public is divided as to whether the Wild and Scenic Rivers Act is the most appropriate mechanism to continue to protect our rivers. Many, including elected officials and the county commissions of both Idaho and Clearwater counties, felt that the Nez Perce-Clearwater already has the best of the best designated as Wild and Scenic Rivers. They said that no other rivers rose to the level of the Lochsa, Selway, Middle Fork Clearwater, and Salmon Rivers. Some suggested that current protections on the rivers, such as PACFISH, the Clean Water Act, and Endangered Species Act, do enough to protect the outstandingly remarkable values. Others expressed that the act originally was meant to protect against dam construction and that dam construction is not likely to be considered on any river on the National Forest. There was widespread agreement that people did not want to see a dam constructed on the North Fork or South Fork Clearwater, or other major rivers, and would support limitations on dam construction. A considerable discussion regarding unintended consequences of suitability, eligibility, or designation brought into question how rivers would be managed and if a suitable finding would curtail forest management, interstate commerce, recreation, and other activities within and outside the corridor. These limitations and their relevance to the economies of local communities was discussed by several, including the county commissions of Idaho and Clearwater counties.

Some of the public appeared to be on the fence regarding finding rivers suitable. They asked that the Nez Perce-Clearwater find the right rivers for the right reasons suitable but not to make it more expansive than it needs to be. During the eligibility process, several rivers rose to the top. These rivers have multiple outstandingly remarkable values, have been reviewed for potential dam construction, and are located outside designated wilderness areas. These rivers generally are the best within their respective subbasins. These rivers also tend to have the most support for a finding of suitable. Others felt an approach that was more holistic was in order and termed this the systems approach. Rivers should not be thought of only as individual rivers or river segments but rather as river systems. Connectivity of high-quality aquatic systems is important for fisheries, wildlife, and recreation. The Nez Perce-Clearwater has some of the best aquatic habitat and rivers in the country. An alternative should be developed that finds many, or most, of the rivers suitable, with a preference on the rivers with the greatest contribution to their subbasin.

Indicators:

- Acres of recommended wilderness areas that provide primitive recreation opportunities.
- Acres of recommended wilderness areas that provide semi-primitive non-motorized recreation opportunities.
- Acres of recommended wilderness areas currently providing semi-primitive motorized recreation opportunities.
- Idaho Roadless Areas providing High and Medium –High Capability for providing wilderness character as assessed using wilderness character attributes of untrammeled, natural, undeveloped, outstanding opportunities for solitude or a primitive and unconfined type of

recreation and Special Features such as Ecological, Geologic, Scientific, Educational, Scenic or Historical Values.

- Idaho Roadless Areas with the potential to add underrepresented ecological communities to the national wilderness system as assessed using number and percentage of underrepresented ecological communities at forest, regional and national landscape scales.
- River segments with outstandingly remarkable values.
- Eligible River segments suitable for inclusion in the Wild and Scenic River system.

Recreation and Access Management

Issue 2: The proposed action may not adequately apportion motorized and non-motorized recreation access opportunities in the front country (Management Area 3) and backcountry (Management Area 2) areas across the Nez Perce-Clearwater.

Background: The Nez Perce-Clearwater currently provides for motorized opportunities on approximately 35 percent of the Nez Perce-Clearwater based on current travel plans. During scoping and in conversations with stakeholders since, it again became apparent that there is a divide between perspectives of how motorized and non-motorized use should be managed. Motorized recreation is very important to the people in the area. Local economies are dependent, in part, on motorized recreation on the Forest. Additional opportunities for motorized recreation should be available in the future. Of particular importance is the opportunity for additional loop systems, including motorized loops of varying length and skill level. In each recreation opportunity, whether roaded modified, semi-primitive, and primitive, there is a desire to be able to access these opportunities with a motorized vehicle in both the winter and summer. Conversely, the forest plan revision team heard some areas of the National Forest should remain free of motorized use. In addition to additional recommended wilderness areas, other areas should not allow motorized use in both the summer and winter seasons. Keeping areas free of motorized use is important for solitude of visitors, to reduce visitor conflict, and to provide habitat for wildlife.

Indicators:

- Acres of Nez Perce-Clearwater currently providing semi-primitive motorized or mechanized opportunity in winter or summer areas that would be managed as recommended wilderness.
- Acres of Nez Perce-Clearwater by use season providing semi-primitive motorized recreation opportunity providing secluded recreation experiences in the backcountry management area (Management Area 2).
- Acres of Nez Perce-Clearwater by use season providing motorized recreation opportunities in the front country (Management Area 3).

Forest Vegetation

Issue 3: Desired conditions for forest vegetation should be met through natural processes or through active management. The rate of progress towards the desired conditions should occur at a faster or slower pace. Desired conditions should include higher compositions of early seral species and increased or decreased patch sizes and increased or decreased tree densities to meet ecological habitat needs of wildlife species, maintain resiliency of forest vegetation communities, and meet the social needs of forest users at a local, regional, and national scale.

Background: Forest vegetation desired conditions were assumed to be an unresolved conflict among available uses. However, as comments came in and through additional conversations with various stakeholders, it became clear that for most the issue was not the desired conditions but how fast the forest moved towards desired conditions, the extent to which active management was used to move towards desired conditions versus letting natural processes dominate, and how special habitats were treated in the plan, such as old-growth forests, snag densities, and live tree retention.

As a result, the forest vegetation desired conditions are nearly identical across alternatives but rather vary by management area and in the rate at which desired conditions are assumed to be met by alternative. Old-growth, snag, and live tree retention plan components also varied by alternative. In general, the public did not comment during scoping regarding the inadequacy of our forest vegetation desired conditions but did comment on how much management was being done, or not done, and how the Nez Perce-Clearwater intended to treat legacy habitats, such as old-growth and snags into the future.

Indicators:

- Forest composition and structure: Predicted changes to tree species composition (dominance types or species presence-abundance) and structure (tree size classes, density, old growth, and snags)
- Landscape pattern of the forests: Potential changes to the pattern of forest conditions (for example, successional stages, species composition, tree density, and fuels) on the landscape
- Resistance and resilience of the forest:
- Response of vegetation to disturbances and stressors — effects of the alternatives on the hazard of wildfire, key insects and diseases, weather disturbances, and climate change
- Carbon stocks

Timber

Issue 4: The Potential Timber Sale Quantity should be increased or decreased to better provide for a balance of ecological sustainability, economic, and social resiliency. The maximum regeneration harvest unit size should be increased or decreased.

Background: Timber harvest and the potential timber sale quantity are directly tied to Issue 3 – Forest Vegetation Desired Conditions. Timber has become a metric used to discuss the amount of activity occurring on the Nez Perce-Clearwater. In this plan, timber volume is an output from the number of acres being treated to achieve desired conditions at various rates that vary by alternative. However, as the public expects a discussion regarding timber outputs, the rule's requirement to state a potential timber sale quantity and the implications the potential timber sale quantity has on local industry and the sustainability of milling infrastructure over time is discussed here as an issue.

Based on acres treated by alternative, the timber harvest levels vary by alternative and range from a level like what is being done currently on the Nez Perce-Clearwater up to a departure from the sustained yield limit to move towards desired conditions at a faster rate. Some would like to see higher levels of potential timber sale quantity to support local communities while others would like to see the highest level that is sustainable in the long-term. Others would rather see natural processes, such as fire, insect and disease, and wind throw, work through time towards forest vegetation desired conditions and would like to see a lesser timber harvest.

Indicators:

- Potential Timber Sale Quantity
- Potential Wood Sale Quantity (includes biomass)
- Maximum regeneration harvest unit size

1.8.2 Non-Significant Issues

While significant issues represent unresolved conflict among available resources; there were numerous other items that may not have been significant in the proposed action were identified through public comment. Those items helped guide the Nez Perce-Clearwater as the forest plan revision team continued to develop plan components and include:

Lolo Trail National Historic Landmark should get special management area protection with a boundary and specific desired conditions

Levels of protections for aquatic resources should be at least as strong as in the Pacific Anadromous Fisheries Strategy (PACFISH)

1.9 Organization and Land Management Plan Components

The detailed plan components for all action alternatives are organized in several parts:

- Chapter 1. Introduction
- Chapter 2. Physical and Biological Ecosystems
- Chapter 3. Tribal Trust Responsibilities
- Chapter 4. Human Uses of the Forest
- Chapter 5. Production of Natural Resources

Land Management Plan appendices include:

- Appendix 1. Maps
- Appendix 2. Glossary
- Appendix 3. Monitoring Plan
- Appendix 4. Management Approaches and Possible Actions
- Appendix 5: Northern Rockies Lynx Management Direction, Record of Decision
- Appendix 6: Water Resources and Fisheries
- Appendix 7: Scenic Character Descriptions.

The following appendices are attached to this Environmental Impact Statement:

- Appendix A: Maps
- Appendix B: Vegetation and Timber Analysis Process
- Appendix C: Wildlife Species and Habitat Summary

- Appendix D: Carbon Assessment
- Appendix E: Recommended Wilderness Inventory, Evaluation, and Analysis
- Appendix F: Wild Scenic River Suitability
- Appendix G: Climate Change
- Appendix H: Scenery Management System Mapping Process
- Appendix I: Comparison of Direction by Alternative
- Appendix J: Lolo Trail Administrative Context and Management Recommendations
- Appendix K: Water Resources and Fisheries
- Appendix L: Air Quality
- Appendix M: Response to Comments

There is an important distinction between plan components, such as desired conditions, objectives, standards, guidelines, and suitability, and other elements of the plan. A plan amendment is required to add, modify, or remove one or more plan components or to change how or where one or more components apply to all or part of the plan area, including management areas or geographic areas (36 CFR 219.13(a)).

Other elements of the Land Management Plan that are not plan components provide information and background material integral to the successful implementation of the Land Management Plan. As conditions change, this information can be updated with administrative changes.

1.9.1 Desired Conditions

A desired condition is a description of specific social, economic, and/or ecological characteristics of the plan area or a portion of the plan area toward which management of the land and resources should be directed. Desired conditions must be described in terms that are specific enough to allow progress toward their achievement to be determined but not include completion dates (36 CFR 219.7(e)(1)(i)).

These are the social, economic, and ecological attributes that will be used to guide management of the land and resources of the plan area. They may apply to the entire plan area or to specific geographic or management areas. Desired conditions are not commitments or final decisions approving projects and activities. The desired condition for some resources may currently exist or may only be achievable over a long time for other resources. The Nez Perce-Clearwater may need to adjust the desired conditions if monitoring results indicate they are not achievable in the long-term. Desired conditions will only be found in the section of the plan labeled “Desired Conditions.”

1.9.2 Objectives

An objective is a concise, measurable, and time-specific statement of a desired rate of progress toward a desired condition or conditions. Objectives should be based on reasonably foreseeable budgets (36 CFR 219.7(e)(1)(ii)).

Objectives describe the focus of management in the plan area within the plan period. Objectives that are defined as occurring “over the life of the plan” are referring to the first 15 years of plan implementation. Objectives will only be found in the section of the plan labeled “Objectives.”

1.9.3 Standards

A standard is a mandatory constraint on project and activity decision making, established to help achieve or maintain the desired condition or conditions, to avoid or mitigate undesirable effects, or to meet applicable legal requirements (36 CFR 219.7(e)(1)(iii)).

Standards can be developed for forestwide application or for specific areas and may be applied to all management activities or selected activities. Standards will only be found in the section of the plan labeled "Standards."

1.9.4 Guidelines

A guideline is a constraint on project or activity decision making that allows for departure from its terms, so long as the purpose of the guideline is met. Guidelines are established to help achieve or maintain a desired condition or conditions to avoid or mitigate undesirable effects or to meet applicable legal requirements (36 CFR 219.7(e)(1)(iv)). Guidelines can be developed for forestwide application or for specific areas and may be applied to all management activities or selected activities. Guidelines will only be found in the section of the plan labeled "Guidelines."

1.9.5 Suitability

Specific lands within the Nez Perce-Clearwater boundaries will be identified as suitable for various multiple uses or activities based on the desired conditions applicable to those lands. The plan will also identify lands within the Nez Perce-Clearwater boundaries as not suitable for uses that are not compatible with desired conditions for those lands. The suitability of lands need not be identified for every use or activity (36 CFR 219.7 (e)(1)(v)).

Identifying suitability of lands for a use in the Land Management Plan indicates that the use may be appropriate but does not make a specific commitment to authorize that use. Final suitability determinations for specific authorizations occur during the project or activity level decision-making process. Generally, the lands on the Nez Perce-Clearwater are suitable for all uses and management activities appropriate for national forests, such as outdoor recreation, range, or timber, unless identified as not suitable.

1.9.6 Management and Geographic Areas

Management areas and geographic areas are spatially identified areas within the Nez Perce-Clearwater. These areas are assigned sets of plan components, such as desired conditions, suitable uses, and, in some areas, either standards or guidelines, or both.

Management Area 1: Wilderness, Wild and Scenic Rivers, and National Historic Landmark Areas

Management Area (MA) 1 is comprised of protected areas with national designations. This management area consists of three sub-categories, each with their own specific management direction. The sub-categories include designated wilderness, designated wild and scenic rivers, and National Historic Landmarks. Components specific to Management Area 1 are coded as "MA1."

Management Area 2: Backcountry

Management Area 2 includes lands within Idaho Roadless Areas, recommended wilderness areas, eligible and suitable wild and scenic rivers, parts of the Gospel-Hump Geographic Area, and proposed and designated research natural areas. This management area is made up of relatively large areas, generally without roads, and provides a variety of motorized and non-motorized recreation opportunities. Trails are the primary improvements constructed and maintained for recreation users. In some areas, lookouts, cabins, or other structures are present, as well as some evidence of management activities. Components specific to Management Area 2 are coded “MA2.”

Management Area 3: Front Country

The rest of the Nez Perce-Clearwater comprises Management Area 3. Most of this management area consists of the areas with roads, trails, and structures, as well as evidence of past and ongoing activities designed to actively manage the area. This management area includes parts of the Gospel-Hump Geographic Area and proposed and designated special interest areas. This management area provides a wide variety of recreation opportunities, both motorized and non-motorized. Components specific to Management Area 3 are coded “MA3.”

Geographic Area: Gospel-Hump

The Endangered American Wilderness Act (1978) divided the roadless area formerly known as the Gospel-Hump area into three portions. The largest portion, consisting of 206,000 acres, became wilderness; another portion, comprising 45,000 acres, became available for immediate development; and a third portion, including three areas totaling 92,000 acres referred to as the Gospel-Hump Multi-Purpose Area, was designated for multiple purpose resource development. Section Four of the Endangered American Wilderness Act directed the completion of the Gospel-Hump Multi-Purpose Plan, which was completed in 1985 and incorporated into the 1987 Nez Perce Forest Plan. The Endangered American Wilderness Act provides for periodic updates to this multi-purpose plan. This section fulfills that legislative intent and would replace the direction for the area found in the Gospel-Hump Multipurpose Resource Development Plan and the 1987 Nez Perce National Forest Land Management Plan.

Geographic Area: Lower Salmon River

The Lower Salmon River area is approximately 210,695 acres and contains a rich geological complexity, contributing to a biological community that is unique within the plan area. This geographic area contains a large portion of the driest portion of the warm dry potential vegetation group dominated by Ponderosa pine under a frequent low intensity fire regime. These habitats support species associated with Ponderosa pine dominated habitats, including several species of conservation concern.

Geographic Area: Pilot Knob

The Pilot Knob geographic area is approximately 20,975 acres is known as T’amloyiitsmexs by the Nez Perce, is a very important cultural and sacred site to the Nez Perce Tribe. T’amloyiitsmexs is a significant landmark used by the Nez Perce for “weyekin,” or spiritual quests. Pilot Knob has a significant historic meaning with respect to the Nez Perce religious values and practices that have been used from time-immemorial and remains to be respected and used by Nez Perce tribal members. Per the Nez Perce Tribal Executive Committee, these tribal religious rites can be conducted in no other place. The Nez Perce Tribe strives to maintain its cultural and traditional practices and to keep alive the knowledge of the beliefs and interpretations of such values. Because of its elevation and central location, Pilot Knob started being used as a site to locate communication equipment in 1977 with the issuance of a communication use permit to the State of Idaho Military Division Public Safety Communications Unit. By 1988, the Nez Perce Tribal Executive Committee described that most of Pilot Knob’s features had been altered, defaced, or destroyed by man-made devices. The Pilot Knob Geographic Area is also an Idaho Roadless Area with a "Special Areas of Historic or Tribal Importance" theme.

Geographic Area: Lolo National Historic Landmark Trail

The Lolo Trail, a National Historic Landmark administered in cooperation with the National Park Service, is part of the Nez Perce National Historical Park. The trail extends through the Nez Perce-Clearwater from Lolo, Montana, to Weippe, Idaho.

The Lolo Trail National Historic Landmark was designated in 1963. Its significance lies in its roots as an ancient American Indian trail. This trail comprises the route Lewis and Clark traveled from 1805 to 1806, as well as the path taken by the Nez Perce Indians during the Nez Perce Indian War of 1877. The landmark stretches about 62 miles from the Nez Perce-Clearwater boundary near Musselshell Meadows to the Nez Perce-Clearwater boundary near Lolo Pass and is approximately 55,760 acres in size.

The Lolo Trail National Historic Landmark is a geographic area and also part of Management Area 1 as a congressionally designated landmark.

1.9.7 Other Required Content

Monitoring Program

The Monitoring Program will provide Land Management Plan monitoring questions and associated indicators. The monitoring plan will offer management of resources on the Plan area, including testing relevant changes and measuring management effectiveness and progress towards achieving or maintaining the plan's desired conditions or objectives per 36 CFR 219.129(a)(2). A Monitoring Plan is included as Appendix 3 of the Land Management Plan.

Priority Watersheds

The 2012 Planning Rule requires that plans identify watersheds that are a priority for maintenance or restoration (36 CFR 219.7(f)(1)). Priority watersheds are identified through the Forest Service Watershed Condition Framework, which is one of the agency's only outcome-focused restoration tools. The Forest Service launched the Watershed Condition Framework in 2010 with the aim of providing a nationally consistent way of assessing watershed condition and prioritizing watershed restoration on national forests and grasslands. Highlighting the value of the Watershed Condition Framework, Section 8405 of the Agricultural Improvement Act of 2018 (2018 Farm Bill) provides specific legislative authorization and requirements for the process, one of those being to identify for protection and restoration up to 5 priority watersheds (Hydrologic Unit Code [HUC] 12) in each National Forest.

Current priority watersheds that have restoration activities in progress include:

- Upper Elk Creek (HUC12 #170603080701)
- Upper Clear Creek (HUC12 #170603040102)
- Upper Little Slate Creek (HUC12 #170602090301)
- Musselshell Creek (HUC12 #170603060202)
- Lower Crooked River (HUC12 #170603050302)

Future priority watersheds will be determined throughout the life of this plan. Priority watersheds are selected by a forest or area responsible official after analysis and evaluation using a multi-functional interdisciplinary approach, with the consideration of:

- Agency watershed restoration policies and priorities that have been established at other scales, including national- and regional-scale restoration strategies.
- The importance of water and watershed resources (resource value), the urgency of management action to address conditions and threats, and economic considerations.
- Alignment with other Forest Service strategic objectives and priorities.
- Alignment with the strategies and priorities of other Federal and State agencies, tribes, community and collaborative efforts, nongovernmental conservation organizations, and public desires.

The participation of partners in the priority selection process is expected and highly encouraged. The 2012 Planning Rule and the planning directives require the responsible official to reach out to local, state, tribal, and other federal agencies and interest groups when identifying priority watersheds (Forest Service Handbook 1909.12, section 22.31). Priority watersheds could occur in watersheds included in the Conservation Watershed Network that require process-based restoration strategies to support ESA listed fish species and Species of Conservation Concern.

By design, Watershed Condition Framework priority watersheds are not intended to be permanent designations - when all needed work is completed, a new Watershed Condition Framework priority watershed is to be identified. Priority areas for potential restoration activities could change quickly because of disturbance events, such as wildfire or severe flooding. Therefore, the 2012 Planning Rule includes priority watersheds as other plan content, so that an administrative change could be used to quickly respond to changes in priority.

Watershed Condition Framework priority watersheds should not be mistaken for INFISH priority watersheds that were selected through the amendment of the 1987 Forest Plans. See Appendix K for more information regarding priority watersheds.

Distinctive Roles and Contributions

The Nez Perce-Clearwater's distinctive roles and contributions are described in Section 1.2.1of the Final Environmental Impact Statement.

Proposed and Possible Actions

A list of proposed and possible actions that could be implemented under this Land Management Plan are included in Appendix 4 – Management Approaches and Possible Actions. This information is not a commitment to take any action and is not a "proposal," as defined by the Council on Environmental Quality regulations for implementing the National Environmental Policy Act (36 CFR 219.7 (e)(1)(f)(iv).

1.9.8 Optional Plan Content

Additional plan content can include information, such as partnership opportunities, coordination activities, or other information to support movement toward desired conditions.

Other content in the Land Management Plan includes:

- Northern Rockies Lynx Management Direction Record of Decision, Appendix 5
- Water Resources and Fisheries, Appendix, Appendix 6
- Scenic Character Description, Appendix 7

1.10 Consistency with Plan Components

As required by the National Forest Management Act, all projects and activities authorized by the Nez Perce- Clearwater must be consistent with the Land Management Plan (16 USC 1604 (i)), per 36 CFR 219.15. This is accomplished by a project or activity being consistent with all applicable plan components.

When a proposed project or activity would not be consistent with the applicable plan components, the responsible official shall take one of the following steps, subject to valid existing rights:

- Modify the proposed project or activity to make it consistent with the applicable plan components.
- Reject the proposal or terminate the project or activity.
- Amend the plan so that the project or activity will be consistent with the plan, as amended.
- Amend the plan contemporaneously with the approval of the project or activity so that the project or activity will be consistent with the plan as amended.

1.10.1 Desired Conditions

Because of the many types of projects and activities that can occur over the life of the Land Management Plan, it is not likely that a project or activity can maintain or contribute to the attainment of all desired conditions, nor are all desired conditions relevant to every activity. For example, recreation desired conditions may not be relevant to a fuel's treatment project. Most projects and activities are developed specifically to maintain or move conditions toward one or more of the desired conditions of the plan. It should not be expected that each project or activity will contribute to all desired conditions in a plan but usually to one or a subset.

To be consistent with desired conditions of the Land Management Plan, a project or activity must be designed to meet one or more of the following conditions:

- Maintain or make progress toward attaining one or more of the Plan's desired conditions or objectives without adversely affecting progress toward the maintenance of other desired conditions or objectives.
- Be neutral with regard to progress toward attaining the Plan's desired conditions or objectives.
- Maintain or make progress toward attaining one or more of the desired conditions or objectives over the long-term, even if the project or activity would have an adverse but short-term effect on progress toward attaining, or maintenance of, one or more desired conditions or objectives.
- Maintain or make progress toward attaining one or more of the Plan's desired conditions or objectives, even if the project or activity would have an adverse but negligible long-term effect on progress toward attaining, or maintenance of, other desired conditions or objectives.

The project documentation will include a finding that the project is consistent with the Plan's desired conditions or objectives and briefly explain the basis for that finding. When a categorical exclusion applies and there is no project decision document, the project must still be found consistent with the revised land management plan.

1.10.2 Standards

A project or activity is consistent with a standard if the project or activity is designed in exact accordance with the standard. The project documentation must confirm that the project is consistent with applicable standards. Deviation from standards requires an amendment to the plan.

1.10.3 Guidelines

A project or activity must be consistent with all guidelines applicable to the type of project or activity and its location in the Land Management Plan area. A project or activity is consistent with a guideline in either of two ways:

- The project or activity is designed in accordance with the guideline, or
- A project or activity design varies from the guideline but is as effective in meeting the intent or achieving the purpose of that guideline.

The project documentation will describe how the project is consistent with the applicable guideline(s). When the project design varies from the exact wording of a guideline, project documentation must specifically explain how the project design is as effective in meeting the purpose of the guideline. Under this circumstance, a plan amendment is not required. However, if a project or activity is not designed to comply with the intent or purpose of a guideline, an amendment to the plan is required.

1.10.4 Hierarchy of Plan Guidance

If conflicting plan guidance is discovered, the following hierarchy will be used to determine which plan components shall be applied in the following order:

1. Designated Wilderness and Designated Wild and Scenic Areas—Management Area 1
2. Lolo National Historic Trail
3. Designated Research Natural Areas
4. Proposed Research Natural Areas, Eligible and Suitable Wild and Scenic Rivers, and Recommended Wilderness
5. Idaho Roadless Rule, unless directed by the rule itself, which supersedes a Land Management Plan
6. Geographic Area Plan Components
7. Management Area Plan Components, other than those listed in 1-5 above
8. Forestwide Plan Components

1.11 Rights and Interests

The Land Management Plan will provide a strategic framework that guides future management decisions and actions. As such, the Plan will not create, authorize, or execute any ground-disturbing activity. The Land Management Plan will not subject anyone to civil or criminal liability and will create no legal rights. The Plan will not change existing permits and authorized uses.

Chapter 2. Alternatives

2.1 Introduction

This chapter describes and compares the alternatives considered by the responsible official for the Land Management Plan. It includes the following:

- a discussion of how the alternatives were developed
- issues raised
- descriptions and comparisons of the alternatives
- a map of each alternative considered

This section also presents the alternatives in comparative form, sharply defining the differences between each alternative and providing a clear basis for choice among options by the decision maker and the public. Some of the information used to compare the alternatives is based upon the design of the alternative, while some of the information is based upon the environmental, social, and economic effects of implementing each alternative.

2.2 Alternatives Considered in Detail

The range of alternatives developed and presented are based on a preliminary evaluation of the information gathered from public and internal comments and the purpose and need for the project. While all alternatives provide a wide range of ecosystem services and multiple uses, some give slightly greater emphasis to select resources based on the theme of the alternative and response to revision topics. The Nez Perce-Clearwater developed six alternatives, including the no action and five action alternatives, in response to issues raised by the public. The alternatives span the range of forest management practices and uses of available resources. The general theme and intent of each alternative is summarized below. A limited number of plan components vary by alternative. Table 4 shows an overview of alternatives.

Four action alternatives were developed based on input, including comments received since the release of the proposed action in July 2014, and through collaboration on alternative development during the winter of 2017-2018. All alternatives analyzed in the Final Environmental Impact Statement met a minimum bar of being ecologically, socially, and economically sustainable per the 2012 Planning Rule. Furthermore, each alternative contributes to rural prosperity and other U.S. Department of Agriculture strategic goals. Alternative themes and their relation to the significant issues are described below.

The action alternatives were developed based on the Nez Perce-Clearwater's Assessment (2014), the need for change, desired conditions, implementation and monitoring of the current forest plan, public meetings, and comments received during the public involvement period, interagency meetings, and meetings with the Nez Perce Tribe. The alternatives represent a range of possible management options from which to choose. Each alternative emphasizes specific land and resource uses and de-emphasizes other uses in response to the revision topics. Some components may vary between alternatives to address the issues identified during scoping; see the description of the alternatives for specific details. Much of the plan direction for desired conditions, standards, and guidelines remains constant for all action alternatives. Where plan direction varies by alternative, the text indicates such. A table of plan components that vary by alterative is included in Appendix H.

2.2.1 No Action Alternative

Under the No Action Alternative, the 1987 Nez Perce and the 1987 Clearwater National Forests' Land Management Plans would continue to provide direction for the combined National Forests unless amended by site specific project implementation. Analysis of a No Action Alternative is a requirement of the National Environmental Policy Act. This analysis reflects the likely outcomes of managing forest lands and resources under the direction of the separate forest plans, into the future. The No Action Alternative for programs associated with an issue statement are as follows.

Recommended Wilderness and Wild and Scenic Rivers

The 1987 Clearwater Forest Plan included the Mallard Larkins, Hoodoo, and Selway additions to Recommended Wilderness Areas, totaling 198,200 acres. These areas have been managed similarly to designated wilderness with respect to motorized and mechanized travel since 2012. Some uses that would be non-conforming in an authorized designated area include administrative use of motorized hand-tools, commercial rental of structures, and the management of fire. Prior to 2012, over the snow winter use was permitted in recommended wilderness areas. That use was ended by the Clearwater Travel Plan Record of Decision.

The Nez Perce National Forest identified no recommended wilderness. While several suitability studies have been initiated in the past, no decisions were made.

Three Wild and Scenic Rivers have been designated on the Nez Perce-Clearwater:

- Middle Fork Clearwater (including the combined flows of the Lochsa River and the Selway River)
- Main Salmon River
- Rapid River

Twenty-nine rivers were found eligible by the 1987 Forest Plans. These rivers have also been identified in the National Rivers Inventory since 1982:

- Bargamin Creek
- Bear Creek Complex – Bear, Cub, Paradis, Brushy Fork, and Wahoo
- Cayuse Creek
- Little North Fork Clearwater
- North Fork Clearwater
- South Fork Clearwater
- Fish Creek
- West Fork Gedney Creek
- Hungery Creek
- Johns Creek
- Kelly Creek
- Lake Creek
- Meadow Creek (Selway)
- Moose Creek Complex – Moose, East Fork Moose, North Fork Moose, West Moose, and Rhoda

- Running Creek
- Salmon River
- Slate Creek
- Three Links Complex – Three Links and West Fork Three Links
- White Bird Creek
- White Sand Creek (renamed Colt Killed Creek)

Recreation and Access Management

The 2017 Clearwater Travel Plan Decision on the Clearwater National Forest dictated allowed and disallowed motor vehicle operation and designated routes. The Forest is open to motorized recreational use except in designated wilderness or as closed by this Travel Plan Decision. No travel plan has been completed on the Nez Perce Forest. The Nez Perce Forest is open to motorized travel except in designated wilderness or closed by a site-specific closure order. Table 1 shows percent area open and closed to motorized use for summer and winter on the Nez Perce-Clearwater based on the Clearwater Travel Plan decision and current closure orders across the Forests.

Table 1. Percent plan area of existing summer and winter open to motorized access under the No Action Alternative

Motorized Access	Summer	Winter
Motorized	55%	63%
Nonmotorized	39%	37%

The 2008 Idaho Roadless Rule[7] identifies 34 Idaho Roadless Areas on the Nez Perce-Clearwater to be managed under the Rule. While the Rule does not speak to motorized use or access, the Rule does place restrictions on timber harvest, road building, and discretionary minerals activities.

The 1993 Clearwater Forest Plan Stipulation for Dismissal mandated that the Clearwater National Forest manage some areas within the Bighorn-Weitas Roadless Area and the North Lochsa Slope Roadless Area similarly to how the National Forest was managing recommended wilderness (no timber harvest and no road construction). For the purposes of the No Action Alternative, these areas are part of the larger Idaho Roadless Area that falls within and where road construction and timber harvest are precluded. For the purposes of the No Action Alternative, they are not considered recommended wilderness areas although management of these areas is similar to that of recommended wilderness.

Recreation opportunity spectrum classes were not used to determine suitability for motorized uses in the 1987 plans. Instead, the 1987 plans used direction from elk habitat effectiveness objectives to identify the appropriate density of motorized roads and trails on the Nez Perce-Clearwater. Direction in the 1987 forest plans required lands to provide for elk by maintaining areas with specified amounts of elk habitat potential. The elk habitat potential standards were associated with land allocations in the 1987 plans and elk habitat effectiveness was the metric used to calculate elk habitat potential.

[7] https://www.fs.usda.gov/main/roadless/idahoroadlessrule

Forest Vegetation

Forest vegetation is treated to increase the dominance of early seral species, including Ponderosa pine, Western larch, and Western white pine. All silviculture systems are used as appropriate, though regeneration harvest is a primary tool for changing dominance types. Reforestation success is generally high in managed stands. Even-aged regeneration harvest unit size above 40 acres requires Regional Forester approval; however, most projects requested are granted this exception to the National Forest Management Act 40-acre limitation based on the silvics of forest stands in north central Idaho.

Old growth is managed per the 1987 Forest Plans, including the 1993 Clearwater Forest Plan Stipulation for Dismissal agreement. Snag and live tree retention are managed consistent with Bollenbacher et al.'s (Bollenbacher et al. 2009a) recommendations, and downed woody debris retention is managed consistent with recommendations by Graham et al. (Graham et al. 1994).

Timber

Timber outputs in the No Action Alternative are assumed to be 50 to 60 million board feet annually, corresponding to a treatment area of 3,000 to 3,500 acres across the Nez Perce-Clearwater. While the Nez Perce-Clearwater is not bound to these volumes, they are a representation of what the current management situation on the Nez Perce-Clearwater is able to produce under the 1987 Forest Plans and amendments.

A slope break of 35 percent is generally used to guide timber harvest by ground-based system versus cable-based systems.

Aquatics

The aquatic ecosystems, fisheries, and water resources programs are based on PACFISH, the associated Forest Plan Amendment, and biological opinion. PACFISH includes a delineation of riparian habitat conservation areas. In practice, activities within Riparian Habitat Conservation Areas have not been conducted on a large scale despite being permitted in some cases within PACFISH. The No Action Alternative assumes that most projects will continue to not propose treatments within Riparian Habitat Conservation Areas.

The Nez Perce Forest Plan includes language to improve aquatic and riparian conditions in watersheds not meeting quality objectives as defined in Appendix A of that plan. In practice, this constraint has been implemented on the Nez Perce-Clearwater by including watershed restoration projects as part of larger vegetation management projects to demonstrate that watershed has an upward trend.

The Clearwater Forest Plan similarly describes watersheds not meeting objectives in Appendix K. The 1993 Stipulation for Dismissal on the Clearwater Forest Plan litigation mandates that any activity in these watersheds yield no net increase of sediment during the project.

The Nez Perce-Clearwater has a very active watershed restoration program, working in partnership with the Nez Perce Tribe, nearby county governmental agencies, and others. The No Action Alternative assumes that these activities continue. Restoration activities are guided by the Watershed Condition framework, the Nez Perce Tribe's Atlas[8], and vegetation management projects approving watershed restoration work as part of larger integrated projects.

---

[8] The Atlas Framework is a tool that prioritizes projects that provide the best value for Columbia River Basin fish. The Nez Perce Tribe uses a Lochsa basin Atlas to help determine priorities for aquatic restoration in that subbasin. For more information visit: https://www.salmonrecovery.gov/doc/default-source/default-document-library/atlas-fact-sheet---aug2015---final.pdf?sfvrsn=2.

Soils

Management of the soil resource in the No Action Alternative is based upon limitations on activities that detrimentally disturb soils and protecting the ash cap. A regional fifteen percent detrimentally disturbed soils cap constrains the amount of ground disturbance that can occur on the Nez Perce-Clearwater. Additionally, on the Nez Perce National Forest, the 1987 Forest Plan includes a twenty percent detrimentally disturbed soils standard. Activities on landslide prone areas, as defined by land types, are restricted. In practice, lands over 55 to 60 percent slope are unlikely to be managed through timber harvest.

Wildlife

The Nez Perce and Clearwater Forests manage habitat to provide for viable populations of species. The Forests' mandate is to manage habitat for species. State wildlife agencies, specifically the Idaho Department of Fish and Game, have the responsibility to manage wildlife population numbers. The Forest Service also has the responsibility for managing tribal treaty trust resources, of which fish and game are critically important to the Nez Perce Tribe. Additionally, the Forests are obligated under the Endangered Species Act (ESA) to aid in recovery of listed species.

The federally listed species in the planning area include Canada lynx (threatened) and wolverine (proposed threatened). Grizzly bear was not included on the U.S. Fish and Wildlife Service list of species that are known to occur on the Nez Perce-Clearwater.

The Nez Perce-Clearwater manages 11 species on the Nez Perce Forest and 15 species on the Clearwater Forest as management indicator species. There are 11 species on the Regional Forester's Sensitive Species List for both the Nez Perce and Clearwater National Forests.

Current management on the Nez Perce-Clearwater emphasizes management of elk and other big game species while providing habitat for other threatened, endangered, sensitive, and management indicator species.

Fire Management

The 1987 plans did not acknowledge that fire was the dominant change agent in the forested ecosystem and should be allowed to play its role across the landscape. Except for wilderness areas and some backcountry roadless areas, aggressive suppression was the primary strategy to manage fire.

The vegetation management strategy for the Nez Perce-Clearwater is to manage the landscape to maintain or trend towards vegetative desired conditions. The tools the Nez Perce-Clearwater has used to move towards desired conditions include hazardous fuel reduction by mechanical treatments, such as timber harvest and hand thinning, prescribed burning, and managing natural wildfire ignitions, for resource objectives. Timber harvest has averaged 4,345 acres per year for the past ten years across the Nez Perce-Clearwater and is expected to increase in pace and scale in the future. Mechanical treatments, such as hand thinning, have accounted for approximately 2,510 acres per year over the past 10 years. Wildland fire, including management ignited prescribed burning and wildfires managed for resource objectives, have accounted for most fuels treatment over the last ten years, accounting for an annual average of 4,346 acres and 35,700 acres respectively.

The 1987 Nez Perce National Forest Plan, as amended, will provide for resource protection and fire use necessary to protect, maintain, and enhance resource values and attain land management goals and objectives. The plan allows for the forestwide use of all management response options for wildfire (control, contain, confine). Exceptions for unplanned ignitions include Management Areas 7, 10, 12 through 15, 17, and 19 through 23. Planned prescribed fire is allowed forestwide. Mechanical treatments are not allowed in wilderness.

The 1987 Clearwater National Forest Plan includes the following forestwide standard: Fire strategies allow for the management of planned or unplanned ignitions to achieve a variety of resource objectives in many of the management areas. Wildfire strategies consist of confine, contain, and control objectives with max acres allowed to burn within each management area. Prescribed fire acres for natural and activity fuels were assigned for each management area. Recreation and research natural areas were not allowed to have unplanned ignitions and were only assigned contain wildfire strategies. Mechanical treatments are not allowed in wilderness.

Livestock Grazing

Livestock owned by local ranchers, referred to as permittees, are permitted to graze within the Nez Perce-Clearwater National Forests under the authority of the Granger-Thye Act of 1950, the Multiple-Use Sustained- Yield Act of 1960, and other federal laws and policies. Thirty-four permittees graze a total of 4,590 head of cattle within 36 active allotted areas, referred to as grazing allotments. There is one permitted sheep allotment with the Nez Perce-Clearwater National Forests, but it is currently inactive due to incompatibility between domestic sheep and native big horn sheep.

Livestock grazing allotments comprise less than 15 percent of the Nez Perce-Clearwater National Forests administered lands. Much of forage capacity for livestock grazing within the Forests is considered transitory in nature, which is forage produced following reduction in conifer overstory associated with fire and timber harvest. Grazing allotments are managed to maintain sustained production of forage, while also meeting the needs of other forest resources, including riparian habitat, threatened and endangered species, native fisheries, wildlife, and recreation. Guidance to grazing permittees regarding management of an allotment is described in a formal Allotment Management Plan and Annual Operating Instructions.

Allotment Management Plans are developed in conjunction with an interdisciplinary review and National Environmental Policy Act analysis of resource issues. Measures to mitigate any identified issues are specified in the Allotment Management Plan and Annual Operating Instructions. Following the listing of steelhead trout and Chinook salmon as threatened species, allotment management has emphasized protection and enhancement of riparian areas, with a focus on streams used by steelhead and salmon. Forest Service administrators routinely inspect grazing allotments for compliance with the objectives and standards specified in the Allotment Management Plan and Annual Operating Instructions.

Energy and Minerals

Mineral resource activities are administered under the appropriate laws and regulations to ensure protection of surface resources while not unduly interfering with mining operations. The national forest provides for reasonable access for mineral prospecting, exploration, development, and production consistent with applicable Land Management Plan direction. Exploration and development of mineral resources is facilitated by providing timely responses to Notices of Intent and Operating Plans. Current emphasis is on working actively with operators to develop adequate mitigations for site-specific resource concerns and to obtain sufficient bonds to cover estimated reclamation needs. The frequency of inspections of ongoing operations is commensurate with their size and complexity, ensure adequacy of operating plans, and identify unforeseen environmental impacts. Reclamation of disturbed areas to a productive condition is required in all cases.

There are approximately 3500 active unpatented mining claims on the Nez Perce-Clearwater. Filing and staking of additional claims tends to fluctuate with the value of certain mineral commodities; however, the trend is generally associated with the value of precious metals. The geology of the Nez Perce-Clearwater generally possesses a low- to high-grade mineralization in many areas. Mineralization could include precious metals, strategic rare earth element deposits, or base metal deposits. Due to a lack of infrastructure, wilderness areas, wild and scenic river corridors, and a low potential of occurrence, the exploration and development of both nonrenewable and renewable energy resources is not expected.

Annually, the Nez Perce-Clearwater administrates Plans of Operation for 40 to 50 suction dredging operations, 3 to 5 placer or lode operations, and 20 to 30 Notices of Intent for mineral exploration.

Small-scale placer and dredging operations continue to be the dominate type of mining on the Nez Perce-Clearwater and are evident because there are no active large or medium sized exploration or mining operations. Table 2 lists waterbodies, timing constraints, and the maximum number of suction dredging operations authorized.

Table 2. Waterbodies, timing constraints, and maximum number of authorized suction dredging operations

Waterbody	Authorized Dates	Maximum Operations
Lolo Creek	July 15 through August 15	18
Moose Creek	July 01 through August 15	38
Orogrande and French Creeks	June 30 through September 15	20
South Fork of the Clearwater River	July 15 through August 15	15

Priorities under the No Action Alternative include:

- Complete an inventory of abandoned mining sites and prioritize sites that pose a risk to human health for permanent closure and reclamation consistent with the management of other surface resources.
- Meet the demand for mineral materials consistent with the management of other surface resources.
- Study existing mineral withdrawals to determine whether to maintain them in that status.
- Request mineral examinations to determine if claims are valid if suspected use is not authorized under mining law or if there is a conflict with other federal uses or regulation.

2.2.2 Alternative W

Resources and land allocation on the Nez Perce-Clearwater are not mutually exclusive. It may be possible to have high levels of timber harvest, sustain rural economies, recover listed fish and wildlife species, provide clean air and clean water, and provide habitat for viable populations of wildlife species all at the same time. For instance, areas evaluated for recommended wilderness are independent from most areas that provide for timber harvest due to the Idaho Roadless Rule. As such, it is possible to recommend all or nearly all Idaho Roadless Rule Areas for recommended wilderness and have a very high level of timber outputs. This thought process led to the idea of a “have it most” alternative. This alternative has higher levels of recommended wilderness coupled with a higher timber output and a faster rate of movement towards forest vegetation desired conditions. Forest vegetation desired conditions would be minimally met within thirty years. Areas not selected as recommended wilderness allow for motorized use, including in the roadless areas. Wild and Scenic Rivers stem from a collaborative approach that looks at rivers outside the wilderness. The intent is to couple items that may otherwise be viewed as being mutually exclusive.

Recommended Wilderness

Alternative W recommends the most areas and the most acreage with ten areas recommended as wilderness, totaling 856,932 acres. These areas would be managed without motorized access in the summer and winter and would not allow mechanized travel.

Suitable Wild and Scenic Rivers

Alternative W includes twelve rivers as suitable wild and scenic rivers.

Access

Alternative W provides for motorized access in all Idaho Roadless Areas with a backcountry restoration theme not recommended as wilderness. Non-motorized access is also greater in this alternative due to the high amount of recommended wilderness that is managed as non-motorized.

Forested Vegetation

Objectives are designed to meet forest vegetation desired conditions for size class distribution and species composition within thirty years.

Timber Harvest

To meet forest vegetation desired conditions, a potential timber sale quantity up to the sustained yield limit of 241 million board feet is expected for the life of the plan.

2.2.3 Alternative X

Alternative X responds to several state and local plans which call for fewer or no areas of recommended wilderness,[9] fewer or no suitable wild and scenic rivers, and higher timber outputs. In this alternative, zero areas are recommended as wilderness. The Idaho State Rivers Program is used as a surrogate to continue to protect key tributaries to the North and South Fork Clearwater Rivers while not pursuing Wild and Scenic River Suitable status on any river. Forest vegetation would be within the lower bound of the desired conditions within twenty years.

Recommended Wilderness

Alternative X allocates zero acres of recommended wilderness.

Suitable Wild and Scenic Rivers

Alternative X allocates zero suitable wild and scenic rivers. Rivers that are referred to in the State of Idaho Department of Water Resources River Plan are managed consistently with that plan, which includes provisions to protect water quality and maintain free flow.

Access

Alternative X allocates the most land as suitable for motorized access both summer and winter.

[9] The Idaho County Natural Resource Plan calls for zero recommended wilderness on the Nez Perce-Clearwater National Forest. The Clearwater County Natural Resource Plan acknowledges that some limited areas of recommended wilderness may be an acceptable tradeoff if other items benefiting rural economies are increased, such as increased timber production

Forested Vegetation
Objectives are designed to meet forest vegetation desired conditions for size class distribution and species composition within twenty years.

Timber Harvest
A departure from the sustained yield limit of 241 million board feet for two decades allows for achievement of desired conditions within that period. This corresponds to an annual potential timber sale quantity of 261 million board feet.

2.2.4 Alternative Y
Alternative Y provides for intermediate level of recommended wilderness and moves towards forest vegetative desired conditions for size class distribution and species composition in fifty years. Historic snowmobiling areas in the Great Burn are removed from consideration as recommended wilderness resulting in a boundary change, but within the areas moving forward as recommended wilderness we do not authorize any uses that may preclude designation as wilderness in the future. This alternative also looks at the major rivers not designated in the Wild and Scenic Rivers Act, including the North Fork Clearwater and South Fork Clearwater, as suitable for inclusion in the Wild and Scenic Rivers system.

Recommended Wilderness
Alternative Y finds four Idaho Roadless Areas as recommended wilderness. This includes a boundary modification of the Hoodoo Roadless Area to allow for over-snow use in two areas that historically has this use prior to the 2012 Clearwater Travel Plan decision. In total, 309,332 acres would be recommended for wilderness. These areas would be managed to not allow over-snow use, motorized use or mechanized travel.

Suitable Wild and Scenic Rivers
Fourteen rivers are found suitable in Alternative Y, including the South Fork Clearwater and North Fork Clearwater.

Access
Access for motorized use is expanded slightly from the No Action Alternative to allow for additional loop opportunities for motorized recreation in several backcountry restoration themed Idaho Roadless Areas including the Bighorn Weitas and Pot Mountain roadless areas.

Forested Vegetation
Forest Vegetation desired conditions are met within fifty years and rely on a combination of active management and natural processes.

Timber Harvest
Timber harvest associated with meeting forest vegetation desired conditions yields a potential timber sale quantity between 130 and 150 million board feet annually.

Other variation in Alternative Y
Alternative Y includes language in the Pilot Knob Geographic Area to not renew the communication site in the future.

2.2.5 Alternative Z

Alternative Z was crafted to respond to requests to have an alternative in which natural processes dominate over anthropogenic influence. In this alternative, a proposal for recommended wilderness that was brought forward by a group of national and state wilderness advocacy groups was mostly carried forward. Additionally, rivers were viewed as part of a larger system, and major tributaries to our largest rivers will be analyzed as being suitable for inclusion in the wild and scenic rivers system. Reliance on natural process would warrant a slower movement towards forest vegetation desired conditions in an anticipated one hundred years or longer. Timber outputs would also be lower and near a lower threshold needed to provide for economic sustainability and sustain rural economies. Additional plan components related to snag guidelines, live tree retention, and elk security are included that limit uncertainty regarding how and where these features will be located on the landscape.

Recommended Wilderness

Recommended wilderness in Alternative Z includes ten Idaho Roadless Areas, totaling 569,755 acres. These areas are managed to allow many uses within them, including uses that would likely not be allowable if designated wilderness by congress in the future. This includes winter motorized over-snow use and mechanized travel.

Suitable Wild and Scenic Rivers

Alternative Z utilizes a system approach to find suitable rivers that forms connection between the headwaters and the main river basins. Thirty-seven rivers are found suitable in Alternative Z.

Access

Access in Alternative Z most closely represents the current levels of access of the No Action Alternative. No major changes are made to the existing condition, other than a geographic area for West Meadow Creek finds that area not suitable for motorized recreation.

Forested Vegetation

Forested vegetation desired conditions would be met over one-hundred-years or longer and would emphasize natural processes before active management.

Timber Harvest

Timber harvest in Alternative Z is projected to be between eight and one-hundred million board feet annually.

Other Variation in Alternative Z

Alternative Z adds additional snag and leave tree requirements when planning timber harvest for any purpose.

2.2.6 Preferred Alternative

The Preferred Alternative was developed following the comment period on the Draft Environmental Impact Statement. This alternative integrates concerns from the public and attempts to find balance and compromise with the major issues. This alternative responds to public comments and is a compilation of portions of all other alternatives analyzed in detail in the Draft Environmental Impact Statement. The Preferred Alternative integrates ecological, social, and economic sustainability while responding to both local and national interests.

Recommended Wilderness

Three recommended wilderness areas would be included in the Preferred Alternative, including parts of four Idaho Roadless Rule areas – Hoodoo, Mallard-Larkins, East Meadow Creek, and West Meadow Creek. The East Meadow Creek Recommended Wilderness Area would be a new recommended area from the No Action Alternative. In total, the Preferred Alternative includes 263,357 acres of recommended wilderness.

Suitable Wild and Scenic Rivers

In the Preferred Alternative, eleven rivers would be found suitable as wild and scenic rivers. In addition, one river with shared jurisdictions, the Little North Fork Clearwater River, would remain eligible.

Access

Opportunities for motorized access decrease in the preferred alternative, in the summer and winter when compared to taking no action and based on the 1987 Plans and closure orders. Approximately fifty-five percent of the Nez Perce-Clearwater would be suitable for motorized use in the summer and approximately sixty percent in the winter. While these opportunities are focused on providing real opportunity for motorized users in both the summer and winter, areas across the Nez Perce-Clearwater where ecological or social reasons dictate a non-motorized experience were delineated as such. These areas include habitat for species such as grizzly bear and wolverine, cross country ski areas, and wintering habitat for some ungulate species.

Forested Vegetation

Forested vegetation desired conditions are predicted to be met in thirty to thirty-five years, resulting from a combination of timber harvest, prescribed fire, and natural disturbance. It is estimated that between 53,000 and 64,500 acres of total disturbance would occur annually.

Timber Harvest

An estimated, 10,000 acres of timber harvest annually would produce between 190 and 210 million board feet annually.

2.3 Alternatives Considered but Eliminated from Detailed Study

Federal agencies are required by the National Environmental Policy Act to rigorously explore and objectively evaluate all reasonable alternatives and to briefly discuss the reasons for eliminating any alternatives that were not developed in detail (40 CFR 1502.14). Public comments received since the scoping period beginning in July of 2014 provided suggestions for alternative methods for achieving the purpose and need. Some of these alternatives may have been outside the scope of this document, duplicative of the alternatives considered in detail, or determined to not meet the purpose and need. Therefore, some alternatives were considered but dismissed from detailed consideration for reasons summarized below.

Reasons for eliminating an alternative from detailed study include, but are not limited to:

- The alternative does not meet the purpose and need.
- The alternative is outside the scope of this environmental impact statement.
- The alternative does not meet law, policy, or regulations.

- The content of the alternative is contained in other alternatives or within the range already being analyzed in detail.

Alternatives considered but eliminated from detailed study are summarized in the following sections. These alternatives include those suggested by many individuals and/or entities. Dozens of other alternatives were also considered but are not listed here. A full listing can be found in the project record.

2.3.1 2014 Proposed Action

As a result of input from scoping comments, the 2014 Proposed Action will not be brought forward or analyzed in the Final Environmental Impact Statement in detail. Many elements of the 2014 Proposed Action will be carried forward into other alternatives. All elements of the 2014 Proposed Action that were not brought forward into another action alternative represent an alternative considered.

2.3.2 2017 Framework for Alternative Development

The framework for alternative development was an interim document used to begin planning conversations on potential alternatives to be considered. While never intended to be analyzed in detail, the framework also represents a variety of plan components considered but ultimately not analyzed in detail. This includes an alternative that had fewer protections for aquatic resources than the PACFISH strategy. Alternatives that allowed for harvest within the riparian reserves, allowed for harvest on all lands prone to mass wasting, and emphasized salvage harvest of timber were also considered.

2.3.3 Timber Target Unconstrained by Budget

Timber industry and collaborative groups have taken a stance on the 2012 Planning Rule's mandate that objectives, including the potential timber sale quantity, be within the fiscal feasibility of the unit. Considering alternatives that are outside the fiscal capability of the unit are not consistent with the 2012 Planning Rule and outside the scope of a Land Management Plan. However, the Nez Perce-Clearwater has taken an all-encompassing vision on fiscal capability, particularly in Alternative X, and factors in full implementation of several initiatives designed to gain efficiency, fund sources other than appropriated dollars, and decrease unit costs when applied at scale. The maximum timber target for every alternative is the sustained yield limit, unless in a departure alternative, and harvest may occur up to that level as funds become available.

2.3.4 Maximum Recreation Alternative

The Idaho County Commissioners requested a "maximum recreation alternative." Elements of all alternatives maximize some aspects of recreation. Many elements of maximizing recreation are site-specific decisions that are outside the scope of a Land Management Plan. Depending on a particular view or desire of recreation, such as motorized versus non-motorized, developed versus dispersed, or primitive versus rural, one alternative may meet your definition of maximizing recreation more than others.

2.3.5 Ecological Processes, a.k.a. "Citizen's Alternative"

The Friends of the Clearwater provided an outline for an alternative endorsed by numerous commenters. This alternative emphasized ecological processes over anthropogenic vegetation management. Elements of this alternative within our scope that meet the purpose and need for action are included as parts of Alternatives W, Y, and Z. For example, in Alternative Z, natural processes dominate over anthropogenic influence. It includes additional plan components related to snag guidelines, live tree retention, and elk security. Timber outputs are projected to be as low as eight million board feet in Alternative Z, well below the current direction (the no action alternative) timber outputs of fifty to sixty million board feet annually.

Alternative W proposes over four times the Recommended Wilderness Area acreage as the current situation, without motorized and mechanized access, while Alternative Z proposes more Wild and Scenic Rivers than the current situation. The plan includes additional proposed Research Natural Areas that do not vary by alternative.

Further, the desired conditions were developed with an emphasis on the natural processes that influence the vegetation on the Nez Perce-Clearwater, as well as appropriate consideration of the impacts of climate change. The plan components also recognize and support the important natural roles of wildfire, insects, and diseases on the landscape, and strives to conserve key ecosystem components such as old growth, snags, and downed woody material as well as connectivity for wildlife species. The plan protects soils and aquatic resources, and the values of suitable wild and scenic rivers.

Certain elements of the citizen's alternative are not addressed to the degree suggested by the commenters, such as managing all roadless areas as recommended wilderness or as non-motorized. This is further discussed in the following alternatives considered but eliminated from detailed study.

Other concepts presented in this alternative do not meet the purpose and need, are not within the scope, or are not within the legal authority of the agency for example, plan direction regarding privatizing the management of public resources or giving the National Forests to the State of Idaho to own or manage. Some proposed plan components are not appropriate, such as standards prescribing National Environmental Policy Act analysis processes.

In summary, this alternative was not analyzed in additional detail because most elements are addressed as appropriate, although not necessarily with the same specific methods (such as standards) as suggested by the commenters.

2.3.6 Additional Areas for Over-Snow Motorized Use

Many snow machine user groups advocated for additional areas for snowmobiling and other winter motorized activities. Alternative X maximizes the amount of over-snow motorized use to the extent allowable by law. Allowing additional areas beyond what Alternative X offers for over-snow motorized use would not meet laws, regulations, and policies that guide this use as well as other multiple uses.

2.3.7 All Idaho Roadless Areas as Recommended Wilderness

Wilderness advocacy groups asked for an alternative in which all Idaho Roadless Areas were added as recommended wilderness. Thirty-three out of the 34 Idaho Roadless Areas went through a wilderness evaluation. Appendix E documents the wilderness evaluation worksheet and narrative for each area. Through this process it was determined that some Idaho Roadless Areas did not fully satisfy one or more wilderness characteristic to warrant consideration or recommendation as wilderness. Detailed analysis is documented in Appendix E of this document. Alternative W provides for the greatest number of acres of recommended wilderness, including about half of the area in Idaho Roadless. Alternatives were also considered that looked at including lands not within Idaho Roadless as recommended wilderness. However, the inventory of areas was determined to be the Idaho Roadless Rule designated areas.

2.3.8 Additional Areas as Recommended Wilderness

Several areas were brought forward by the public in scoping comments that were not included in the Idaho Roadless Rule evaluation and, therefore, were not included in this recommended wilderness inventory or analysis. Those areas included Goddard Creek, Kelly Mountain, North Siwash, Middle Fork

Face, Rudd Moore Lakes, and Wendover. The comments included the recognition that these areas likely would not warrant consideration as recommended wilderness for various reasons.

A review identified that Goddard Creek and Kelly Mountain were considered in the Roadless Area Review and Evaluation (RARE II), (U.S. Department of Agriculture 1979) and dropped as inventoried roadless areas during the Idaho Roadless Rule process. Given that these areas had been inventoried and dropped from further consideration, there was no reason to consider them further. Middle Fork Face, Rudd Moore Lakes, and Wendover areas are all less than 5,000 acres, are not contiguous to any wilderness or recommended wilderness area and were not considered in RARE II. North Siwash was reviewed and found to have had logging operations each decade since the 1960s and, therefore, had cumulatively degraded wilderness character. Following direction in Forest Service Handbook 1909.12, Chapter 70, 71.1, the Nez Perce-Clearwater reviewed these areas and determined they did not meet the criteria in the Forest Service Handbook 1909.12, Section 71.2.

Public comments also brought forward areas referred to as the Gospel-Hump additions. These included areas commonly known as Indian Creek, Johns Creek, Tenmile Creek, and Boulder Creek. These areas were also considered in RARE II (U.S. Department of Agriculture 1979) and dropped as inventoried roadless areas during the Idaho Roadless Rule process. Given that these areas had been inventoried and dropped from further consideration, there was no reason to consider them further. In addition, in 1978, the Endangered American Wilderness Act (Public Law 95-237) established the Gospel Hump Wilderness. The Act designated approximately 92,000 acres adjacent to the Wilderness "as generally depicted on said map" as management areas to be managed in accordance with a multipurpose resource management plan for multiple uses. The development of this plan was also required by the Act. Indian Creek, Johns Creek, and Tenmile Creek comprise these management areas. Given that management of these areas had been established through legislation, they were not included in the roadless inventory.

The Act also identified about 45,000 acres "generally depicted on said map" as development areas to be immediately available for resource utilization under the existing applicable Forest Service Land Management Plans. The Committee on Energy and Natural Resources submitted a report to accompany H.R. 3454. Maps of the areas were included in that report. That report includes the statement: "the committee expects the Forest Service to cease all further study it might contemplate undertaking with regard to the suitability and desirability of congressional designation of the lands within the 'development' and 'management' areas as components of the National Wilderness Preservation System." These development areas included areas adjacent to the east, north, and west boundary of the Gospel Hump Wilderness and include the area of Boulder Creek. Given the Congressional intent as stated in the Committee on Energy and Natural Resources report, those areas were not included in the roadless inventory.

Furthermore, Forest Service Manual 1920 –Land Management Planning, 1920.3 – policy states that plan revisions that were initiated prior to the issuance of the amended directive in 2015 are not required to revise past steps or phases of the process. For example, a completed assessment, including the wilderness inventory, does not need to be revised to comply with the amended directives. The assessment and evaluation of wilderness inventory was conducted in 2013, prior to the finalization of the planning regulation implementation directives at Forest Service Handbook 1909.12 in 2015, and, therefore, did not require revision.

2.3.9 Additional Eligible Wild and Scenic Rivers and Fewer Eligible Wild and Scenic Rivers

Many stakeholders, including river advocacy groups, suggested the list of wild and scenic eligible rivers in the scoping documentation was not complete. Many outstandingly remarkable values were suggested, and groups suggested the list was not long enough or comprehensive enough. Other stakeholders, including Clearwater County and Idaho County, suggested that the list was too long and that the list contained more than the "best of the best." Since 2015, the interdisciplinary team looked at all named rivers on the Forests and made new eligibility determinations. These determinations do not vary by alternative per the directives as a river either has outstandingly remarkable values or not. Eighty-eight rivers on the Nez Perce-Clearwater were found to be free flowing AND have outstandingly remarkable values. The results of the eligibility process have been documented and available to the public: https://www.fs.usda.gov/detail/nezperceclearwater/landmanagement/planning/?cid=fseprd552493.

2.3.10 No Wild and Scenic Rivers Suitability Study

As the Wild and Scenic Rivers eligibility process does not vary by alternative, the Nez Perce-Clearwater was asked to complete a suitability study to determine which rivers would be suitable for inclusion in the Wild and Scenic Rivers System. A few groups suggested that approach may not be legal or appropriate and suggested the Nez Perce-Clearwater not pursue a suitability study and manage eligible rivers under interim protection. The 2012 Planning Rule requires that National Forests include the evaluation of rivers for potential inclusion as a Wild and Scenic River under the Wild and Scenic River Act of 1968. Eligible rivers determined suitable for inclusion in the National Wild and Scenic River system should be included in the development or revision of Land Management Plans (Forest Service Handbook 1909.12, Chapter 80). The interim management of eligible or suitable rivers must then have interim protect measures until a decision is made on future use of the river though an Act of Congress. The Nez Perce-Clearwater proceeded with a suitability study along with the revision of the Land Management Plan.

2.3.11 Manage Eligible Rivers Under Interim Guidance

Once a wild and scenic rivers suitability study is complete, eligible rivers found not suitable need not be managed under interim protection measures (Forest Service Handbook 1909.12) therefore this alternative was considered but not analyzed in detail. Rather, these eligible rivers are managed under the guidance of the Land Management Plan with whatever guidance would otherwise apply. Some asked that the Nez Perce-Clearwater consider management of eligible rivers under interim direction regardless of the results of a suitability study.

2.3.12 Include All 88 Eligible River Segments as Suitable

All eligible river segments were evaluated to determine if they could be suitable in one or more alternatives. Fifty-two river segments were not found suitable following completion of the handbook process for determining suitability.

While these rivers possess values that were considered outstandingly remarkable, other resource opportunities and concerns within and/or adjacent to these river corridors were determined to warrant management actions that would be inconsistent with management direction under wild and scenic classification. Considering these opportunities and concerns, as well as the ability to protect these river values through other regulatory and administrative means, contributed to the finding that those rivers are not suitable when applying the suitability criteria (Forest Service Handbook 1909.12, Chapter 80). They were therefore not considered further in the evaluation process. Appendix F provides the details for the Wild and Scenic River suitability analysis.

2.3.13 All Idaho Roadless Areas as Non-Motorized

Groups requested that an alternative be considered that assigns non-motorized classifications to all Idaho Roadless Rule Areas or all Recommended Wilderness Areas. Alternatives W and Y and the Preferred Alternative do manage all recommended wilderness as non-motorized. However, managing all the Idaho Roadless Areas as non-motorized would preclude valid and existing multiple uses from occurring on the Forest and would be inconsistent with laws, regulations, and policies. Idaho Roadless Areas (that have not been identified as Recommended Wilderness Areas under the Preferred Alternative) will continue to be managed consistently with the Idaho Roadless Rule. Motorized and nonmotorized equipment as well as mechanized travel by the public would not be suitable in recommended wilderness areas. While the Rule does not speak to motorized use or access, the rule does place restrictions on timber harvest, road building, and discretionary minerals activities within Idaho Roadless Areas.

2.3.14 Specified Motorized Road and Trail Densities

Requests from groups, as well as from Idaho County and Clearwater County, asked that the draft Land Management Plan include desired conditions, standards, or guidelines for routes (roads and trails) open to motorized use. Some desire thresholds set by management area, watershed, or game management unit. Some see these densities as a minimum density to guarantee a minimum and predictable level of motorized access. Others look at densities as a cap on motorized routes to reduce impacts to fish and wildlife. While the alternatives do provide for differing levels of motorized use through the recreation opportunity spectrum and suitability plan components, currently no threshold for minimum or maximum densities of routes is prescribed. The suggested approach was considered and discussed at length. Designated routes and areas for motorized use are addressed in travel planning. While the Land Management Plan sets the stage for travel planning, the plan is not travel planning and becoming too specific may limit the range of possible solutions during travel planning. The action alternatives use suitability to describe motorized access. Alternatives are analyzed that increase areas suitable for motorized access in both summer and winter to respond, in part, to the concerns of the counties. Action alternatives also focus on desired conditions for access—desiring roads in the correct places to provide for a valid multiple use and providing motorized access while preventing harm to ecological resources, including fish and wildlife, remaining silent on the site-specific route density needed to accomplish this desired condition.

2.3.15 Add Plan Components for Trail Maintenance in Recommended Wilderness Areas

Some commenters suggested an alternative that adds plan components to address trail and vegetation maintenance in recommended wilderness areas to outline appropriate methods that would not affect wilderness character or future designation. These commentors suggested that administrative use of mechanized or motorized equipment should not be suitable in Recommended Wilderness Areas.

In all alternatives, except Alternative Z, recreational motorized and mechanized trail use would not be suitable in Idaho Roadless Areas recommended for wilderness. However, many of these trails are expected to stay in place and suitable for non-motorized and non-mechanized recreational use. Generally, all system trails on the Nez Perce-Clearwater are expected to receive routine maintenance approximately every three years on a rotating basis. With the exception of designated wilderness areas, these maintenance activities have included, and are expected to continue the use of motorized and mechanized equipment. The scale of these activities is small, their duration is short, they are proven to protect and improve trail and resource conditions and would be similar under all alternatives.

Forest Service Handbook 1909.12 Chapter 70 states that the responsible official has discretion to implement a range of management options, including options that enhance the ecological and social characteristics that provide the basis for wilderness designation and options that continue existing uses. It was determined that the use of chainsaws and other motorized or mechanized equipment would be suitable when such use would accomplish restoration activities that protect or enhance the wilderness characteristics of the area, maintains infrastructure and trails, or facilitates access, resource protection, or user safety. It was recognized that these activities could potentially have short-term impacts to user solitude and opportunity for primitive or unconfined recreation if back-country visitors were in proximity of these activities where they could be seen or heard. It was also recognized that such activities could have short-term disturbance to nearby wildlife for the duration of the activity. However, it was also determined that these short-term impacts would have no lasting effects on wilderness character or potential for future designation. It was determined that the objectives of such motorized or mechanized use could have long-term effects that preserve or enhance wilderness character that far exceed the duration of the short-term impacts.

Given the potential for long-term benefits to wilderness character of motorized and mechanized administrative use and considering that potential for short-term impacts would not have long-lasting effect on wilderness character or future designation, it was determined that further detailed analysis of this use versus non-use was not warranted. Therefore, the effects from these activities were not analyzed in further detail.

2.4 Comparison of Alternatives

This section provides a summary of the effects of implementing each alternative. Information in the table is focused on activities and effects where different levels of effects or outputs can be distinguished quantitatively or qualitatively among alternatives.

2.4.1 Management Areas by Alternative

Management area acres are presented in table 3 by alternative.

Table 3. Management area acres by designated area and alternative (Alt)

Management Area	No Action[1]	Alt W	Alt X	Alt Y	Alt Z	Preferred
1(a)-Designated Wilderness	1,139,059	1,139,059	1,139,059	1,139,059	1,139,059	1,139,059
1(b)-Designated Wild and Scenic Rivers	57,891	57,891	57,891	57,891	57,891	57,891
1(c) National Historic Landmark	55,760	55,760	55,760	55,760	55,760	55,760
MA1 subtotal	1,231,638	1,231,638	1,231,638	1,231,638	1,231,638	1,231,638
2(a) Idaho Roadless Areas	1,481,636	1,481,636	1,481,636	1,481,636	1,481,636	1,481,636

[1]No Action Alternative numbers are estimates to compare against alternatives. The 1987 Forest Plans had dozens of management areas.

[2]Forest Acreage numbers represent the administrative Nez Perce-Clearwater boundary.

2.4.2 Overview of Alternatives

An overview of alternatives considered in detail is included in Table 4, including the No Action Alternative (“No Action”), Alternative W (“Alt W”), Alternative X (“Alt X”), Alternative Y (“Alt Y”), Alternative Z (“Alt Z”), and the Preferred Alternative (“Preferred”).

Table 4. Overview of alternatives (Alt)

Resource Topic	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Recommended Wilderness	Hoodoo, Mallard-Larkins, Portions of : North Fork Spruce-White Sands and Sneakfoot Meadows	Bighorn-Weitas, Hoodoo, North Lochsa Slope, Mallard-Larkins, East Meadow Creek, Moose Mountain, Rapid River, North Fork Spruce-White Sands, Sneakfoot Meadows, Meadow Creek-Upper North Fork	None	East Meadow Creek; Hoodoo with Boundary change to create GA for snowmobiling; Mallard Larkins; Rapid River	East Meadow Creek, West Meadow Creek, Hoodoo, Mallard-Larkins, Meadow Creek-Upper North Fork; North Fork Spruce-White Sands, Rapid River, Rawhide, Sneakfoot Meadows, Pot Mountain	Mallard Larkins (82,286 acres); Hoodoo (108,276 acres) and East Meadow Creek (72,795 acres)
Mechanized or Motorized Recreation Uses in Recommended Wilderness	No over-snow motorized travel. No summer motorized or non-motorized mechanized travel. Motorized and non-motorized mechanized equipment suitable for administrative use.	No over-snow motorized travel. No summer motorized or non-motorized mechanized travel. Motorized and non-motorized mechanized equipment suitable for administrative use	n/a	No over-snow motorized travel. No summer motorized or non-motorized mechanized travel. Motorized and non-motorized mechanized equipment suitable for administrative use	Winter over-snow motorized travel allowed. Summer mechanized travel allowed. No motorized summer travel. Motorized and non-motorized mechanized equipment suitable for administrative use.	No winter motorized travel, no summer motorized or non-motorized mechanized travel. Motorized and non-motorized mechanized equipment suitable for administrative use.
Wild and Scenic Eligible and Suitable Rivers	0 Suitable, 29 Eligible: Bargamin Creek; Bear Creek Complex (Bear, Brushy Fork, Cub, Paradis, Wahoo); Cayuse Creek; Fish Creek; Hungery Creek; Johns Creek; Kelly Creek; Lake Creek; Little North Fork Clearwater River; Meadow Creek (Selway); Moose Creek Complex (East Fork Moose, Moose, North Fork Moose, West Fork Moose Creek, Rhoda); North Fork Clearwater River; Running Creek; Salmon River; Slate Creek; South Fork Clearwater River; Three Links Creek Complex (Three Links, West Fork Three Links); West Fork Gedney Creek; White Bird Creek; White Sand Creek (renamed Colt Killed Creek)	12 Suitable: Cayuse Creek, Fish Creek, Hungery Creek, Johns Creek, Kelly Creek, Little North Fork Clearwater River, Meadow Creek (Selway), Middle Fork Kelly, North Fork Kelly, Salmon River, South Fork Kelly, Weitas Creek	0 Suitable: manage 21 rivers consistent with the Idaho Department of Water Resources "State Protected Rivers" direction. North Fork Clearwater River Subbasin: North Fork Clearwater River, Weitas Creek, Elk Creek, Isabella Creek, Beaver Creek, Elmer Creek, Kelly Creek, North Fork Kelly Creek, Middle Fork Kelly Creek, South Fork Kelly Creek, Cayuse Creek, Little North Fork Clearwater River South Fork Clearwater Subbasin: American River, Johns Creek, Gospel Creek, West Fork Gospel Creek, Meadow Creek, Red River, Silver Creek, South Fork Clearwater River, West Fork Crooked River	14 Suitable: Cayuse Creek, Fish Creek, Hungery Creek, Johns Creek, Kelly Creek, Little North Fork Clearwater River, Meadow Creek (Selway), Middle Fork Kelly Creek, North Fork Clearwater River, North Fork Kelly Creek, Salmon River, South Fork Clearwater River, South Fork Kelly Creek, Weitas Creek	37 Suitable: Systems Approach: Bargamin Creek, Bear Creek, Big Sand Creek, Bostonian Creek, Boundary Creek, Brushy Fork Creek, Buck Lake Creek, Caledonia Creek, Colt Killed Creek, Crooked Fork Creek, Cub Creek, East Fork Meadow Creek (Selway), East Fork Moose Creek, Fish Creek, Graves Creek, Hungery Creek, Johns Creek, Kelly Creek, Little North Fork Clearwater River, Meadow Creek (South Fork Clearwaeter River), Middle Fork Kelly Creek, Moose Creek, North Fork Kelly Creek, North Fork Moose Creek, North Fork Storm Creek, Rhoda Creek, Running Creek, Sabe Creek, Salmon River, Silver Creek, South Fork Kelly Creek, South Fork Storm Creek, Storm Creek, Upper Lochsa River, Weitas Creek, West Moose Creek, Wounded Doe Creek	11 Suitable: Cayuse Creek, Fish Creek, Hungery Creek, Weitas Creek, Kelly Creek, North Fork Kelly Creek, Middle Fork Kelly Creek, South Fork Kelly Creek, Colt Killed Creek, Meadow Creek (Selway) and the Salmon River. 1 Eligible: Little North Fork Clearwater River
Access	Clearwater travel plan; site specific closure orders in some areas on the Nez Perce Forest (no travel plan in place)	All Backcountry Restoration IRA's motorized ROS in summer; most areas open in winter	More summer motorized access, Motorized loop opportunities expanded in MA2	Motorized loop opportunities expanded in MA2	Similar to existing condition in summer, increased winter motorized	More summer and winter motorized access. Important areas for non-motorized access in the future delineated.
Percentage of Forest in Motorized ROS Category	Summer: 61%	Summer: 47%	Summer: 58%	Summer: 44%	Summer: 43%	Summer: 55%
Percentage of Forest in Motorized ROS Category	Winter: 63%	Winter: 48%	Winter: 70%	Winter: 62%	Winter: 70%	Winter: 60%
Percentage of Forest in Non-Motorized ROS Category	Summer: 39%	Summer: 53%	Summer: 42%	Summer: 56%	Summer: 57%	Summer: 45%
Percentage of Forest in Non-Motorized ROS Category	Winter: 37%	Winter: 52%	Winter: 30%	Winter: 38%	Winter: 30%	Winter: 40%
Acres of Disturbance or Restoration Annually to be within Natural Range of Variability[1]	40,000	53,000-64,500	53,000-64,500	53,000-64,500	53,000-64,500	53,000-64,500
Timber Harvest Acres annually	4,300	12,600	14,000	7,500	3,700	8,825-10,000
Timber Output Restoration potential timber sale quantity	50-60 MMBF	221-241 MMBF	241-261 MMBF (Departure)	120-140 MMBF	60-80 MMBF	190-210 MMBF
Max Regen Unit Size	40 acres	207 acres	207 acres	207 acres	207 acres	207 acres

[1] Disturbance acres include wildfire, prescribed fire, timber harvest and other fuels treatments designed to meet desired conditions and be consistent with NRV.

2.4.3 Activities Suitable in Recommended Wilderness

A summary of proposed activities suitable in recommended wilderness is presented in Table 5 by alternative.

Table 5. Summary of proposed activities suitable in recommended wilderness by alternative (Alt)

Proposed Activity	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Motorized Travel	No	No	n/a	No	Yes- Winter Motorized	No
Mechanized Travel	No	No	n/a	No	Yes	No
Motorized and mechanized tools for public use	No	Hand-Held Motorized allowed (for example, Chainsaws)	n/a	No	Yes	No
Motorized and mechanized tools for administrative use	Yes	Hand-Held Motorized allowed (for example, Chainsaws)	n/a	No	Yes	Yes
Aircraft landing for recreational use	No	No	n/a	No	Yes	No
Aircraft landing for administrative use	Yes	Yes	n/a	Yes	Yes	Yes

Chapter 3. Affected Environment and Environmental Consequences

3.1 Introduction

This chapter presents the existing environment of the Nez Perce-Clearwater National Forest, hereinafter referred to as the "Nez Perce-Clearwater," plan revision project area and the potential consequences to that environment that may be caused by implementing the alternatives described in Chapter 2. Within each resource section, the boundaries of the area used for the resource analysis are disclosed. The discussion of resources and potential effects take advantage of existing information included in the 2014 Assessment, other planning documents, resource reports and related information, and other sources, as indicated. Where applicable, such information is briefly summarized and referenced to minimize duplication. The discussions here refer to the potential for the effect to occur and are in many cases only estimates. The effects analyses are useful when comparing and evaluating alternatives on a forest-wide basis but is not intended to be applied directly to specific locations on the national forest.

This final environmental impact statement is a programmatic document. It discloses the environmental consequences on a large scale at the planning level. This contrasts with analyses for site-specific projects. The final environmental impact statement presents a programmatic action at a forest level of analysis but does not predict what will happen each time the standards and guidelines are implemented. Environmental consequences for individual, site-specific projects on the Nez Perce-Clearwater are not described. The environmental effects of individual projects will depend on the implementation of each project, the environmental conditions at each project location, the application of standards and guidelines in each case, addressed with the appropriate level of NEPA documentation.

The affected environment and environmental consequences discussions in this chapter allow a reasonable predication of consequences on the Nez Perce-Clearwater. However, this document does not describe every environmental process or condition.

The land management plan provides a programmatic framework that guides site-specific actions but does not authorize, fund, or carryout any project or activity. Because the land management plan does not authorize or mandate any site-specific projects or activities, including ground-disturbing actions, there can be no direct effects. However, there may be implications or longer-term environmental consequences of managing the Nez Perce-Clearwater under this programmatic framework.

3.1.1 Budget Levels

The Nez Perce-Clearwater's budget directly affects the level of activities and outputs that may occur through Land Management Plan implementation. Funding appropriated by congress is expected to remain flat or decrease in the future. Budgets include appropriated funds, as well as other sources of funding, such as retained receipts from timber sales, money available to accomplish work in stewardship contracts, partnership dollars, and other trust fund accounts. Overall, the amount of funding available to accomplish work on the Nez Perce-Clearwater is expected to increase as the amount of timber harvest increases. In alternatives in which timber harvest does not increase, available funding is expected to remain constant. Objectives assume that current appropriated funding levels would be maintained; however, as activity increases additional funding would be available to perform other restoration work on the Nez Perce-Clearwater. Alternatives that include additional timber harvest assume additional non-appropriated funds are available to support an increase in other non-timber related restoration objectives. Objectives in some alternatives also assume efficiencies in planning and implementation are realized, reducing planning and implementation costs and the time required. To analyze effects without consideration of expected budgets would be a misrepresentation of expected outcomes. The exception is the vegetation, timber, and fire management resource sections. To display movement towards vegetation desired conditions and to develop the sustained yield limit, an unconstrained budget level was analyzed along with constrained, current budget level.

3.1.2 Relevant Laws Common to All Resource Areas

The following laws, regulations, and policy are relevant to all, or nearly all, resource areas. Each section may also include additional relevant laws, regulations, and policies specific to that resource area.

The Multiple-Use Sustained-Yield Act of 1960 set the stage for the management of national forests by specifying that they would be administered for outdoor recreation, range, timber, watershed, and wildlife and fish purposes. Renewable surface resources should be administered for multiple use and sustained yield to best meet the needs of the American people without impairment of the productivity of the land.

The Forest and Rangelands Renewable Resources Planning Act of 1974 provides for maintenance of land productivity and the need to protect and improve the soil and water resources.

Under the National Forest Management Act (1976a), "It is the policy of the Congress that all forested lands in the National Forest System shall be maintained in appropriate forest cover with species of trees, degree of stocking, rate of growth, and conditions of stand designed to secure the maximum benefits of multiple use sustained yields. Plans developed shall provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area to meet the overall multiple-use objectives, and within the multiple-use objective." This act also provided specific direction, including, but not limited to, the development of land management plans and silvicultural requirements, such as maximum even aged harvest openings and reforestation requirements.

3.1.3 Chapter 3 Organization

Chapter 3 of this document is organized into the following sections:

- 3.1 Introduction
- 3.2 Physical and Biological Ecosystems
- 3.2.1 Forestlands
- 3.2.2 At Risk Plant Species
- 3.2.3 Climate Change and Forest Carbon
- 3.2.4 Fire Management
- 3.2.5 Invasive Species
- 3.2.6 Soil Resources
- 3.2.7 Water Resources
- 3.2.8 Aquatic Ecosystems and Fisheries
- 3.2.9 Wildlife
- 3.2.10 Air Quality

- 3.2.11 Ecology
- 3.3 Tribal Trust Responsibilities
- 3.4 Human Uses
- 3.4.1 Cultural Resources
- 3.4.2 Sustainable Recreation
- 3.4.3 Scenery
- 3.4.4 Infrastructure
- 3.4.5 Land Ownership and Land Uses
- 3.5 Production of Natural Resources
- 3.5.1 Timber
- 3.5.2 Energy and Minerals
- 3.5.3 Livestock Grazing
- 3.6 Designated and Recommended Areas
- 3.6.1 Designated Areas
- 3.6.2 Recommended Areas
- 3.6.3 Research Natural Areas
- 3.6.4 Special Areas
- 3.7 Risk Management & Safety
- 3.8 Economic and Social Environment
- 3.8.1 Economic Sustainability
- 3.8.2 Social Sustainability
- 3.9 Concluding Information and Disclosures

3.2 Physical and Biological Systems

3.2.1 Forestlands

This report discusses the coarse filter characteristics of terrestrial ecosystems on the Nez Perce-Clearwater, including both forested and non-forested plant communities. The coarse-filter approach discusses conditions at the ecosystem or plant community level in terms of providing for ecosystem integrity and diversity.

Key ecosystem characteristics are defined in the 2012 Planning Rule as "the dominant ecological components that describe ecosystems and are relevant to ecosystem condition and integrity as well as land management concerns." Vegetation ecosystem integrity is assessed through the characteristics listed in table 6. These characteristics were identified in the Nez Perce-Clearwater Forest Plan Assessment as measurable components of ecosystem integrity or were identified through public scoping. They are measurable and described quantitatively or qualitatively. The desired condition for each characteristic and its relationship to current and potential future conditions form the basis for this analysis.

Table 6. Terrestrial vegetation key ecosystem characteristics

Characteristic	Indicator	Measure
Vegetation composition	Dominance types (forested and non-forested)	Percent of area
Size class distribution	Classes based on basal area weighted diameter	Percent of area
Forest density	Classes based on canopy cover density	Percent of area
Landscape resilience	Resilience indicators	Insect and disease hazard ratings; Projected wildfire; Landscape pattern and patch size
Rare or Unique habitat element	Aspen prevalence	Percent of area
Old Growth	Resilient old growth	Percent of area

Vegetation management includes timber harvest, fuel reduction, restoration, and salvage. Public scoping identified a need for more active or less active vegetation management. The alternatives were formulated with this in mind, and this analysis focuses on effects to indicators from varying management intensities and practices. Separate sections deal with additional vegetation characteristics and issues, including fire and fuels, carbon storage, timber outputs, and at-risk plant species.

Changes Between Draft and Final Environmental Impact Statement

Multiple changes were made for this document; however, all changes are within the scope of the Draft Environmental Impact Statement analysis and discuss issues that the public has had an opportunity to comment on. This section details the key changes between the draft and final analysis for terrestrial vegetation. See the timber section also, as the modeling changes between these resources are interconnected.

Analysis was added for the Preferred Alternative. With respect to vegetation, this alternative is like all action alternatives, with one distinction being in the objective functions used in the timber scheduling model (PRISM), as described in the timber section and Appendix B. A minimum value for long term sustained yield was incorporated into the PRISM runs for the Preferred Alternative.

Updated specific measures for landscape resiliency to replace vegetation condition class with projected wildfire. Projected wildfire is used as a measure of desired condition attainment related to the natural range of variation for wildfire frequency and severity without reference to specific vegetation types as with vegetation condition class.

Updated acreage calculations for each management area by alternative. This was in response to the GIS analysis of boundaries associated with recommended wilderness for each alternative. These updated acreage estimates are very small and do not affect desired conditions for terrestrial vegetation.

Updated tables and narrative surrounding discussions of the distribution and frequency of broad potential vegetation type by forestwide and management area scales. This update is in response to incorporating data from the updated R1 Hybrid 2015 data set which included remeasured Forest Inventory and Analysis (FIA) plots which provided an updated estimate of numerous vegetation characteristics including dominance types, size class, and density metrics at various scales.

Incorporated a large-tree structure analysis into the size class discussions to illustrate how each alternative affects large tree recruitment. The large-tree structure analysis is also used to illustrate the relationship between large tree distributions and old growth forest structure on the forest.

Updated insect and disease hazard ratings based on updated R1 Hybrid 2015 FIA data set.

Included additional discussions relating the current distribution of old growth types to natural disturbance regimes including wildfire. The old growth discussion has been expanded to include a discussion relating old growth types to old growth forest cover types and the relationship to dominance types and habitat type groups and included tables to illustrate both the metrics used to define old growth, old growth forest cover types, and the disturbance processes which give both rise and decline of old growth on the forest.

Updated the forest density section and incorporated updated **Sim**ulating vegetation **P**atterns and **P**rocesses at **L**andscape Sca**LE**s (SIMPPLLE) output data to collaborate the effects of natural disturbance processes and vegetation treatments on forest density.

Updated existing condition estimates for dominance types, size class, and canopy cover classes based on updated R1 Hybrid 2015 FIA data set.

Updated desired condition ranges for dominance type and size class based on updated natural range of variation (NRV) analysis which incorporated an updated climate model with improved predictive performance of regional climate scenarios.

Updated average opening patch size and area weighted mean opening patch size based on updated NRV analysis. Included a Jenks Natural Breaks algorithm analysis to better describe the variance of opening size distributions.

Incorporated the preferred alternative into vegetation analysis, ecosystem consequences, and conclusion sections including the projected modeling outcomes for changes in dominance types, size class, and density.

On April 20, 2023, the USDA issued a technical report in fulfillment of Biden Executive Order 14072, Section 2(b) (U. S. Department of Agriculture and U.S. Department of the Interior 2023 (14072 2023)). This report provides definitions for mature and old-growth forests and an initial inventory of these conditions on lands managed by the Forest Service and Bureau of Land Management. This report presents the finding that the Forest Service and Bureau of Land Management lands combined contain 32.7 +/- 0.4 million acres of old-growth and 80.1 +/- 0.5 million acres of mature forest, representing 18 percent and 45 percent of all forested land managed by the two agencies, respectively. This initial national inventory was conducted by applying the old-growth and mature working definitions to Forest Inventory and Analysis field plot data. To provide the initial inventory, the department provided narratives and working quantitative definitions for old-growth and mature forest for each Forest Service region.[10]

To quantify and estimate old growth, the authors of the technical report utilized Old Growth Forest Types of the Northern Region (Green et al. 2011) which has been used to define old growth in the Northern Region for decades. Prior to the mature and old growth report produced in response to President Biden's Executive Order (14072 2023), there was not a consistent definition of "mature forest." The quantitative definition presented in the technical report is considered a "working" definition appropriate for application for the national-scale inventory. As mentioned in the "Mature and Old-Growth Forests: Definition, Identification, and Initial Inventory on Lands Managed by the Forest Service and Bureau of Land Management," the working definitions developed for the national inventory may need "further refinement… to apply working definitions at local scales due to diverse ecology, forest types, site characteristics, and varied management contexts" (14072 2023). At this time, the working definition has not been refined to the local scale; therefore, we do not currently have a quantitative estimate of mature forest on the Nez Perce-Clearwater National Forests.

Relevant Laws, Regulations, and Policy

Federal Laws

Multiple-Use Sustained-Yield Act of 1960: This act set the stage for the management of National Forests by specifying that they would be administered for outdoor recreation, range, timber, watershed, wildlife, and fish purposes. Renewable surface resources shall be administered for multiple use and sustained yield to best meet the needs of the American people without impairment of the productivity of the land.

Forest and Rangelands Renewable Resources Planning Act of 1974: This act provides for maintenance of land productivity and the need to protect and improve soil and water resources.

National Forest Management Act of 1976: The act specifies "it is the policy of the Congress that all forested lands in the National Forest System shall be maintained in appropriate forest cover with species of trees, degree of stocking, rate of growth, and conditions of stand designed to secure the maximum benefits of multiple use sustained yields. Plans developed shall provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet the overall multiple-use objectives, and within the multiple-use objective." This act also provides specific direction in areas such as the development of land management plans and silviculture requirements, including maximum even aged harvest openings and reforestation requirements.

Methodology

Spatial Scale

The Nez Perce-Clearwater plan components focus on the need to conserve dynamic, multi-scale ecological components, structures, and processes that sustain a full complement of native species and their supporting ecosystems. This report documents the coarse filter analysis of the terrestrial ecosystems. Other reports focus on species-specific conditions, resources, and management strategies under a fine filter approach.

The affected area for terrestrial vegetation is the lands administered by the Nez Perce-Clearwater as illustrated in Appendix A. This area represents the National Forest System lands where changes may occur to vegetation because of management activities or natural events. Information is summarized at three scales:

Forestwide to provide information on the broad scale context. This scale is appropriate as it is an ecological boundary that includes the broad scale vegetation and ecological trends in a contiguous land area as recommended by the Council of Environmental Quality's publication Considering Cumulative Effects under the National Environmental Policy Act[11].

Broad potential vegetation group because indicators, such as species dominance and density, vary by site capability.

Management area because the unique disturbance history and human uses of each area has and will continue to influence vegetation.

Effects to forest vegetation under each alternative are analyzed by potential vegetation type group within each management area. The management area split was done in response to a request from the public. The Nez Perce-Clearwater was divided by potential vegetation type group due to the varying ecological capacities and differing natural conditions for each potential vegetation type group. The rationale behind splitting the landscape by management area was that each management area has different tools available for management and different objectives for management. Because of this, the landscape was partitioned for analysis, monitoring, and development of desired conditions to reflect those differences. This was done to balance the types of disturbances used to meet objectives. For instance, if all management areas were grouped together, setting a desired condition for up to 40 percent of the warm moist potential vegetation type group to be in an early successional stage possibly could result in much of that 40 percent being in Management Area 3, where timber harvest is the primary tool to achieve desired conditions. As a result, much more than 40 percent of the front country may be harvested to reach the desired conditions

[11] National Environmental Policy Act, NEPA.gov. Available online: https://ceq.doe.gov/publications/cumulative_effects.html#:~:text=Considering%20Cumulative%20Effects%20Under%20the,additional%20information%20and%20background%20data

while fire suppression kept a large portion of the roadless areas in a mid-to-late successional stage. Conversely, using the same example, if fire swept through Management Area 1 and Management Area 2, causing 40 percent of the warm moist potential vegetation type group to be in the early successional stage, timber harvest would no longer be useable as a tool in Management Area 3 to create more of the early successional stage. The idea was to create balance in how different tools were used to achieve desired conditions.

The affected area for cumulative effects also includes lands of other ownership within and immediately adjacent to the forest boundaries. The cumulative effects analysis will discuss how the vegetative landscape may be affected by each alternative in the analysis area when considering other past, present, and foreseeable future actions.

Temporal Scale

The temporal scale of this comparative analysis is 150 years. Quantitative effects were derived from the SIMPPLLE and PRISM models, which use whole decades as the modeling time steps. Action alternatives are designed to achieve desired conditions at different time steps in the 150-year modeling scenario. For this reason, a comparative time step approach is used to compare achievement of desired conditions between alternatives. All alternatives are analyzed at both 20 years and 50 years to provide a short-term and long-term comparative time step. The model is programmed to maximize objective functions specific to each alternative. Alternative W is designed to achieve desired conditions within 30 years, Alternative X within 20 years, Alternative Y within 50 years, Alternative Z within 100 years, and the Preferred Alternative between 35 and 40 years. Each alternative is expected to achieve different results relative to forest cover type, size class, and density distributions. All alternatives, including the No Action Alternative, are expected to have different impacts and effects related to other resources, such as acres of prescribed fire needed to accomplish objectives, acres of lynx and fisher habitat affected by wildland fire, mean opening patch size, and distribution of patches. Ultimately, each alternative is assessed relative to attainment of Land Management Plan desired conditions and objectives.

PRISM analysis models were run for 150 years to assess the stability of vegetation communities following proposed silviculture treatments and natural disturbance regimes. SIMPPLLE model runs of 1,000 years were used to capture forest succession and development under the natural range of variation influenced by climate cycles and various disturbance agents. An analysis of the natural range of variation was a primary element that informed desired conditions. The natural range of variation provides a frame of reference for ecological integrity and resilience. It reflects the conditions that have sustained the current complement of wildlife and plant species and provides context for understanding the natural diversity of vegetation and the processes that sustain it. Since the mid-1800s, human presence and activities have increased dramatically in the plan area. Natural range of variation estimates provide a reference to conditions that might have occurred prior to these impacts. The intent of using the natural range of variation to inform desired conditions is not to return precisely to conditions that occurred at a single point in time but to understand the full range of conditions that were supported prior to substantial human influence. Desired conditions are framed within the variability associated with the natural range of variation to provide context for management objectives.

Desired condition development and methodologies

This section discusses the factors and rationale applied in the development of desired conditions for vegetation in the Nez Perce-Clearwater Land Management Plan. Since the Draft Environmental Impact Statement, changes have been made to desired conditions based on internal and public comment as well as an updated natural range of variation (NRV) analysis (Appendix B of this final EIS). The desired conditions are included as plan components and form the basis of the timber and vegetation future modeling to compare alternatives. Please see the Land Management Plan for detailed definitions of each desired condition.

The NRV shows the mean percentage for the dominance type and size class attributes, with ranges around the 5 and 95 percentiles, rounded to the nearest percentage. Existing condition estimates are shown as the mean with ranges depicting the 90 percent confidence interval. The desired condition ranges are based on the NRV ranges; however, rounding occurs to not place undue confidence on model precision. Generally, the ranges span at least 5 percent for uncommon elements and 10 percent for more common elements. For example, if the NRV predicted a range of 6–8 percent, the desired condition range may be 5–10 percent. In addition, either the lower bound, upper bound, or both modeled NRV ranges are adjusted in specific cases to account for best available science information (BASI) regarding the historic condition or potential future condition of the attribute. When such adjustments are made, in most cases, the desired condition ranges overlap either the high or low end of the NRV range. Specific literature used to support adjusted desired conditions is cited in each attribute section.

Some attributes cannot be modeled with SIMPPLLE (that is, snags, old growth, coarse woody debris, etc.). For these elements, other resources are used to inform plan components.

Natural Range of Variation as a basis for desired conditions

An analysis of the NRV was a primary element that informed desired conditions. The NRV provides a frame of reference for ecological integrity and resilience. It reflects the conditions that have sustained the current complement of wildlife and plant species and provides context for understanding the natural diversity of vegetation and the processes that sustain it. Since the mid-1800s human presence and activities have increased dramatically in the plan area. The NRV estimates provide a reference to conditions that might have occurred prior to these impacts. The intent of using the NRV to inform desired conditions is not to return to conditions that occurred at a single point in time, but rather to encompass the full range of conditions that were supported prior to substantial human influence (Wiens et al. 2012).

The future will not be the same as the past. The NRV does not provide insight into conditions that may vary in the future or other considerations relative to social demands placed on the ecosystem. Further, the analysis includes inherent uncertainty, and it is appropriate to utilize additional resources, including literature, to ensure the “envelope” of vegetation conditions described by desired conditions will meet future ecological and social needs. Therefore, the desired conditions are not always equal to the NRV because additional factors were considered as noted in the detailed sections below.

Forest Service Handbook (FSH) 1909.12 Land Management Planning Handbook recognizes there may be other factors (social, economic, or ecological) that lead the responsible official to determine that the NRV may not be an appropriate desired condition for certain characteristics. These considerations include maintaining conditions that contribute to long-term resilience given uncertainties in future climate and disturbances, sustaining stand structures or species compositions that provide habitat for at-risk wildlife or plant species, conserving rare structures or components, existing or anticipated human use patterns, the effects changing climate may have, and ecosystem services expected from forest lands (such as reduction of fire hazard). The following factors are considered in the development of vegetation desired conditions: manage vegetation to generally be within the NRV, maintain conditions that would contribute to long-term ecosystem resilience and adaptation to uncertainties of future climate and disturbances, sustain important wildlife habitat conditions, and consider social and economic factors.

Research indicates there is potential for ecological transformations to occur in temperate ecosystems, based on the potential for interrelated drivers such as chronic and acute drought, wildfire, and insect outbreaks to push ecosystems beyond their thresholds for resilience (Millar and Stephenson 2015, Golladay et al. 2016). In some cases, management intervention might be able to ease the transition to new forest states and minimize losses of ecosystem services (Millar and Stephenson 2015). We do not have the capability to predict such possible shifts at the local scale. By basing the desired conditions around the NRV, with a focus on maintaining the full suite of ecosystem diversity and components that enhance resilience to disturbance, the Land Management Plan would guide management toward maintaining functioning ecosystems in the face of uncertainty.

Recent studies and analyses have been conducted regarding the appropriateness of using the NRV to frame desired conditions (Hansen et al. 2018, Timberlake et al. 2018). In both cases, the authors found that using the NRV provided a solid and defensible base to inform future desired conditions.

Halofsky et al. (2018) documents the results of a literature review and analysis of data by a variety of subject matter experts examining the ecosystems of the Northern Rocky Mountain forests and specifically the region encompassing the Nez Perce-Clearwater. This document determined that “managing toward the NRV is a reasonable approach given the available data, current state of the forest ecosystem and projected future change.” The authors examined the vulnerability of ecosystems on the Nez Perce-Clearwater to climate change and delineated potential adaptation and restoration strategies, which are consistent with the recent work of the Northern Rockies Adaptation Partnership, which is the BASI for climate change in Region 1.

Haugo and Welch (2014) developed an assessment of ecosystems, vulnerabilities, and restoration needs in cooperation with The Nature Conservancy and the Clearwater Basin Collaborative. The authors allow that NRV may help inform the desired future condition, but also promote that current departure from NRV is reflective of departure from historic fire regimes. The report discusses ecosystem integrity in the face of climate change by evaluating dominant ecosystem characteristics and functions.

The issue of using a historical range of variability in the context of climate change is discussed in Climate Change Vulnerability and Adaptation in the Northern Rocky Mountains (Halofsky, Peterson, et al. 2018a), as shown in Box 1. The Nez Perce-Clearwater is consistent with the concepts presented, by considering the full range of NRV conditions to establish desired condition ranges (not precise targets) that are adjusted where need to reflect other BASI.

Box 1: From (Halofsky, Andrews-Key, et al. 2018). Box 6.1 – Using Historic Range and Variability to Assess and Adapt to Climate Change

- “To effectively implement ecosystem-based management, land managers often find it necessary to obtain a reference or benchmark to represent the conditions that describe fully functional ecosystems (Cissell et al. 1994; Laughlin et al. 2004). Contemporary conditions can be evaluated against this reference to determine status, trend, and magnitude of change, and to sustainable condition (Hessburg et al. 1999; Swetnam et al. 1999). Reference conditions are assumed to represent the dynamic characteristics of ecosystems and landscapes, varying across time and space (Swanson et al. 1994; Watt 1947).
- The concept of historical range and variability (HRV) was introduced in the 1990s to describe past spatial and temporal variability of ecosystems (Landres et al. 1999), providing a spatial and temporal foundation for planning and management. HRV has sometimes been equated with “target” conditions (Harrod et al. 1999), although targets can be subjective and somewhat arbitrary, they may represent only one possible situation from a range of potential conditions (Keane et al. 2009). HRV encompasses a full range of conditions that have occurred across multiple spatiotemporal scales.

- HRV represents a broad historical envelope of possible ecosystem conditions—burned area, vegetation cover type area, patch size distribution—that can provide a time series of reference conditions. This assumes that (1) ecosystems are dynamic, not static, and their responses to changing processes are represented by a past variability; (2) ecosystems are complex and have a range of conditions within which they are self-sustaining, and beyond this range they make a transition to disequilibrium (Egan and Howell 2001); (3) historical conditions can serve as a proxy for ecosystem health; (4) the time and space domains that define HRV are sufficient to quantify observed variation; and (5) the ecological characteristics being assessed for the ecosystem or landscape match the management objective (Keane et al. 2009).
- The use of HRV has been challenged because a warmer climate may permanently alter the environment of ecosystems beyond what was observed under historical conditions (Millar et al. 2007a). In particular, disturbance processes, plant species distribution, and hydrologic dynamics may be permanently changed (Notaro et al. 2007). However, a critical evaluation of possible alternatives suggests that the HRV might still be the most viable approach in the near term because it has relatively low uncertainty.
- An alternative to HRV is forecasting future variations of landscapes under changing climates by using complex empirical and mechanistic models. However, the range of projections for future climate from the commonly used global climate models may be greater than the variability of climate over the past three centuries (Stainforth et al. 2005). This uncertainty increases when we factor in projected responses to climate change through technological advances, behavioral adaptations, and population growth (Schneider et al. 2007). Moreover, the variability of climate extremes, not the gradual change of average climate, will drive most ecosystem response to climate mediated disturbance and plant dynamics (Smith 2011) that are difficult to project. Uncertainty will also increase as climate projections are extrapolated to the finer scales and longer time periods needed to quantify future range and variability (FVR) for landscapes (Araujo et al. 2005; Keane et al. 2009)."

There is literature that indicates a high likelihood of future scenarios wherein the suite of ecosystems present today and in the NRV are no longer resilient to change and transform into novel ecosystems. In other words, conditions may shift outside of the NRV, and ecosystem integrity may no longer be measured by that yardstick, therefore, desired conditions built around NRV may not be achievable. The risks for species shift and loss of forest cover due to drought and disturbance are acknowledged; however, these scenarios are generally predicted to occur in the longer term (beyond the 15-year planning cycle) and are difficult if not impossible to quantify at the scale of a National Forest. The specific configuration of potentially new ecosystem conditions is not quantifiable due to the level of uncertainty associated with future climates, and any attempt to craft desired conditions to capture the suite of conditions that may be sustainable in 50 years or more would be based on substantial guesswork and downscaling of larger modeling efforts.

The NRV for wildfire and insect activity places the analysis into context with historic regimes (see Appendix B). Wildfire is, was, and will remain the dominant ecosystem driver. Given the importance of fire as a key ecosystem process, maintaining vegetation and forest diversity, sustaining fire adapted species and structures, and creating vegetation conditions that support and sustain native wildlife species in the short and long term are critical components of the Plan. Management Area 3 is still demonstrating the lack of fire that has occurred throughout the era of fire exclusion and remains well below the NRV for acres burned; Management Areas 1 and 2 are reflecting the trend of increasing fire activity with warming climates. It is likely that insect and disease occurrence may increase with continued warm and dry climates during the life of the plan. However, recent mountain pine beetle and defoliating insect outbreaks may preclude many areas from infestation for several decades.

Past, Present, and Future Activities used in the Analysis

Effects analysis presented for each alternative includes estimates of acres burned because of wildfire which are managed for resource benefit. Not every natural ignition will be suppressed. Wildfires originating within Management Areas 1 and 2 will likely be allowed to burn to achieve landscape level objectives. Wildfire originating in Management Area 3 will likely be suppressed to protect human life and private property, particularly within the wildland urban interface and forest management investments such as plantations. Application of the national cohesive strategy for wildland fire management will have impacts to forest density objectives within the wildland urban interface and other special emphasis areas.

Significant acreage within the administrative boundary of the Nez Perce-Clearwater has been designated as roadless under the Idaho Roadless Rule. These lands are subject to management limitations, which will have an impact on the extent to which forestwide management objectives can be met.

Designation of sub-management areas, such as 1A2C-Suitable Wild and Scenic River, within designated wilderness are not likely to have any effect on vegetation management proposals given that these areas are currently within designated wilderness. There are approximately 42 sub-management areas defined within the Land Management Plan. Of these, recommended wilderness areas are likely to have the greatest effect on forest management objectives over time.

Changes in regional climate will affect the nexus between current and future forest conditions and vegetation condition class. Potential fire effects to vegetation are likely to change because of changing climate.

The Idaho Department of Fish and Game has proposed a change in the management emphasis for elk habitat. Elk habitat management should focus on developing and maintaining high quality forage. This management focus is commensurate with the wildlife resource objectives proposed by the Nez Perce-Clearwater. As such, the Idaho Department of Fish and Game elk habitat management proposal is not likely to have an impact on the attainment of vegetation objectives.

Analysis Methods and Assumptions

Management Area

There are three management areas defined for the purpose of analyzing alternatives under this Land Management Plan. Management Area 1 (MA1) contains areas designated by Congress and includes designated wilderness, designated wild and scenic rivers, and national historic landmarks and trails. Management Area 1 is managed to be consistent with the legislation for each area designation. Generally, these areas are part of the National Preservation System and are managed for preservation emphasis in which natural processes are the primary means of disturbance.

Management Area 2 (MA2) is referred to as the back-country area and contains areas designated by the executive branch, generally by the Secretary of Agriculture or the United States Forest Service. Designated areas within Management Area 2 include Idaho Roadless Rule areas, recommended wilderness, suitable wild and scenic rivers, the Gospel Hump multi-purpose area, designated Research Natural Areas, and proposed Research Natural Areas. These areas are managed consistent with the rule or plan direction in which it was designated for. Some areas have specific direction spelled out, such as the Idaho Roadless Rule. Others are managed for a specific purpose solely based on Land Management Plan direction. Generally, these lands are managed to preserve the characteristics or value for which they were designated, such as roadless character, outstandingly remarkable values, and areas for scientific research. Management often is a combination of letting natural processes dominate and promoting active management. The degree to which nature is allowed or how human influences affect change through management is variable within each sub-management area. The sub-management area categories of this management area may vary by alternative if they are designated in one alternative but not another. Timber harvest is permitted in some portions of this management area, while prescribed fire is generally permissible across the management area. Some portions of Management Area 2 are suitable for timber harvest while others are unsuitable. No areas in Management Area 2 are suitable for timber production.

Management Area 3 (MA3) is referred to as the front-country and contains areas without special designation. Management Area 3 is managed for multiple uses within the constraints of forest practices, regulations, laws, and special management restrictions. Active management is the dominant disturbance agent in this management area. Within this management area, ecological, social, and economic factors are given equal weight. The land is managed under a conservation ethos and is managed consistent with the Forest Service mission statement. Timber harvest may be used to meet desired conditions of many resources. All areas suitable for timber production are within Management Area 3.

Table 7 and Table 8 lists the acres by land status and management areas across all alternatives. To provide meaningful context for comparison across all alternatives, the management area designations are superimposed onto the administered lands of both the Nez Perce and Clearwater National Forests which represents the No Action Alternative.

Table 7. Land status acres by alternative.

	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Administrative Forest Boundary	4,074,832	4,074,832	4,074,832	4,074,832	4,074,832	4,074,832
Non-Forest Service Lands	135,775	135,775	135,775	135,775	135,775	135,775
Forest Service Lands	3,939,056	3,939,056	3,939,056	3,939,056	3,939,056	3,939,056

Broad potential vegetation groups

Terrestrial vegetation characteristics are stratified by broad potential vegetation group, which identify sites of similar environmental conditions. These groups provide information on the inherent capability of the land to support vegetation and the nature of change in vegetative communities over time. Broad potential vegetation groups are groupings of potential vegetation types and potential vegetation types are groupings of habitat types. These hierarchical classifications are summarized as follows.

Habitat type is a fine-scale site classification based on physical and environmental similarities, which result in similar potential plant communities and ecological processes. The designation of habitat types is based on the potential climax plant community (Pfister et al. 1977). Climax conditions represent the culmination of the plant community that would occur through natural succession in the absence of stand replacing disturbances. Though the general characteristics of the climax plant community may be the same on sites of the same habitat type, existing plant communities could be very different at any one point in time due to factors unique to each site, such as the history, pattern, and frequency of disturbance.

Potential vegetation types combine habitat types into areas of similar climate, slope, soils, and other biophysical characteristics. A map layer was developed in 2004 (Jones 2004) to depict potential vegetation groups, which is currently the only available layer that provides a consistently derived and contiguous map of potential vegetation types across the Forest Service Northern Region.

Broad potential vegetation type groups provide more coarse groupings of habitat types for purposes of broad level analysis and monitoring. Region 1 produced a detailed description of these groups and how potential vegetation types and habitat types are nested (Milburn et al. 2015). These groups serve as the basis for description and analysis of ecological conditions at the forestwide and landscape scales. Areas within each of the groups would have similarities in patterns of potential natural plant communities, potential productivity, natural biodiversity, and ecological processes.

Table 9 illustrates the distribution of broad potential vegetation types within each management area. Differences in relative distributions of broad potential vegetation types between management areas gives rise to differences in species compositions and relative species abundance.

Table 9. Distribution of broad potential vegetation types (PVT) within each management area (MA).

	Percent of MA 1	Percent of MA 2	Percent of MA 3
Cold PVT	26%	10%	4%
Cool Moist PVT	34%	30%	13%
Warm Dry PVT	31%	26%	32%
Warm Moist PVT	8%	34%	49%
Non-forested	2%	1%	2%

Table 10 displays the proportion of each forestwide broad potential vegetation group associated with dominance types prevalent within the plan area. Four forested broad potential vegetation types – warm dry, warm moist, cool moist, and cold – are found on the Nez Perce-Clearwater. In addition, five non-forested types – alpine, riparian or wetland, xeric shrub or woodland, mesic grassland, and xeric grassland – plus sparsely vegetated areas are located on the Nez Perce-Clearwater. Dominance types associated with each broad potential vegetation type are listed for each management area in Table 10. A map is available in Appendix A.

Table 10. Forestwide cover dominance types and associated broad potential vegetation type groups.

Dominance Type	Cold	Cool Moist	Warm Dry	Warm Moist
Ponderosa pine	0%	0%	16.4%	1.2%
Douglas fir	2.8%	19.0%	31.5%	24.1%

Dominance Type	Cold	Cool Moist	Warm Dry	Warm Moist

Subalpine fir	26%	34%	0%	1%
Whitebark pine	0%	0%	0%	0%

[1]Approximately 2.5% of the western redcedar dominance type within Management Area 3 is composed of western hemlock (*Tsuga heterophylla*), which occurs only in the warm moist potential vegetation type group.

Data Source: R1 Hybrid 2015 Data Set.

Dominance Type

Dominance type is determined by the species with the greatest abundance of canopy cover, basal area, or trees per acre within a setting or map feature. The species that determine the dominance type are always of the same lifeform. Therefore, it is necessary to first identify the dominant lifeform and tree lifeform subclass before determining dominance type (Barber et al. 2011).

Dominance type is not an expression of total species composition or species presence for a map feature or forested stand. The species having a plurality of canopy cover, basal area or trees per acre determines the dominance type. Other species are generally present within a mapped feature or forested stand but occur at lower percentage amounts. For example, a forested stand may be classified as a grand fir (*Abies grandis*) dominance type based on having the largest percentage of basal area but may also contain Douglas fir (*Pseudotsuga menziesii*), Western larch (*Larix occidentalis*), and Ponderosa pine (*Pinus ponderosa*). The total species assemblage is a function of the habitat type, forest succession, and disturbance history. Refer to Appendix B for a description of species presence for each management area.

Currently, the plan area is dominated by mid and late seral species, such as grand fir, subalpine fir (*Abies lasiocarpa*), and Engelmann spruce (*Picea engelmannii*) dominance types; however, many of these areas would have historically been dominated by long-lived early seral species, such as Ponderosa pine, Western larch, Western white pine (*Pinus monticola*), and whitebark pine (*Pinus albicaulis*). The percentages of current forest cover types by management area are displayed in the tables within this section.

Historically, Western white pine was the most important forest cover type in North Idaho, occupying the region's cooler moister sites in elevations between 2,000 and 5,500 ft. (Haig 1932). Because of the shade intolerance of Western white pine, successful fire suppression efforts in the 1900s discouraged the continued reproduction of this tree species, as did the introduction of white pine blister rust. Due to the lack of stand replacing disturbances and lack of naturally occurring blister rust resistant seed sources on the landscape, Western white pine is being supplanted by more shade tolerant and more disease susceptible species, including grand fir and Douglas fir (Fins et al. 2001). Site specific observations in the project area verify these general observations made by Fins(2001). In the stands proposed for vegetation management, the most abundant species are shade tolerant species rather than long-lived early seral species, such as Western white pine, Ponderosa pine, or Western larch.

The warm dry broad potential vegetation group occupies the warmest and driest sites on the Nez Perce-Clearwater that support forests. These sites support Ponderosa pine, Douglas fir, and dry site grand fir habitat types. This group occurs at lower elevations, on warm southerly aspects, and on droughty soils. Forests are often dominated by Douglas fir and Ponderosa pine along with Western larch as a minor component. Open forest savannas may occur within this group where grasses or shrubs are dominant, and trees are widely scattered due to repeated frequent fires.

The warm moist group includes some of the most productive forest sites on the Nez Perce-Clearwater. Distribution of this group is highly influenced by aspect, slope position, and seasonal fluctuations in water tables. On drier sites, grand fir is the dominant climax species north of the North Fork Clearwater River. Western hemlock (*Tsuga heterophylla*) dominates the wetter end of this group with western redcedar (*Thuja plicata*) dominating on cooler and wetter sites south of the North Fork Clearwater River. This setting occurs on mid-to-high elevation sites across all aspects. Historically, Western white pine is the most common seral species dominant within this group, along with grand fir, Western larch, and Douglas fir.

The cool moist group comprises the most productive subalpine-fir and Engelmann spruce sites on the Nez Perce-Clearwater. Moist mountain hemlock (*Tsuga mertensiana*) and lodgepole pine (*Pinus contorta*) habitat types are in this group, along with subalpine fir and spruce habitat types. This setting occurs on mid-to-high elevation sites across all aspects. Lodgepole pine and Engelmann spruce are the most common seral species.

The cold broad potential vegetation group occupies the highest elevation areas that support forests. Some sites are cold, moderately dry subalpine fir habitat types that support moderately dense forest cover. Remaining areas are cold drier mountain hemlock and lodgepole pine. At the timberline, whitebark pine and subalpine larch types are dominant where growing conditions are harsher and tree density more open.

Non-forest broad potential vegetation groups consist of the persistent non-forested vegetation climax types. They occur on sites where establishment and growth of conifers is impeded, for example in areas of shallow or very droughty soils; very wet soils and high-water tables; or very frequent disturbance. Persistent non-forested areas include alpine meadows, dry grasslands and shrublands, mesic grasslands, and riparian areas. There are also areas on the Nez Perce-Clearwater that are non-vegetated where very sparse or no vegetation grows, such as scree or barren areas. These are excluded from the analysis.

Forest Density

Forest density is a measure of the area occupied by trees. The density of trees can influence tree growth and vigor; susceptibility to drought, insects and diseases, wildfires, and windthrow potential; and the rate of forest succession, as well as other attributes such as vertical structure. These factors, in turn, affect whether the stand is suitable habitat for certain wildlife species. For this analysis, tree canopy cover is used as the measure of density because it is the only spatially explicit measure of forest density available for analysis. Tree canopy cover data is derived from the VMap product (see Appendix B) and tracked through spatial projections in the SIMPPLLE model. Canopy cover is the percentage of ground covered by a vertical projection of the outermost perimeter of the tree crowns, considering trees of all heights. Density is reported as the percent of canopy cover associated with tree species and is analyzed across all potential vegetation type groups and management areas to evaluate effectiveness in meeting plan objectives.

Canopy cover is low when the stand is in the earliest stage of succession and dominated by seedlings. As trees grow, crowns expand to fill up growing space and canopy cover gradually increases. Growth of understory trees over time also adds to the canopy cover and vertical structure as the forest grows into the later successional stages. Disturbances and competition-based mortality can limit tree density. Site productivity also affects canopy cover, with more productive moist sites supporting higher densities and harsh sites with poor soils supporting lower densities. Frequent fire, particularly in the warm dry potential vegetation group, can maintain low canopy covers at all stages of forest succession.

Forest density influences tree species composition and vice versa. For example, Ponderosa pine and lodgepole pine are intolerant of shade and cannot survive in the lower canopy layers. Shade tolerant species, such as subalpine fir and spruce, can prosper in dense stand conditions with limited light. Unless a disturbance reduces competition from shade tolerant species, intolerant species will die out. Some cover types, such as lodgepole pine, naturally grow at high density. Others, such as Ponderosa pine, typically grow at more open densities with natural disturbance regimes.

Vertical structure is not a key indicator, nor does it have quantitative desired conditions; however, it is described in conjunction with density. Vertical structure is categorized as a single-storied, one canopy layer; a two-storied, two canopy layers; or a multistoried, three or more canopy layers. As with density, vertical structure is driven by succession, individual species traits, and disturbances. Some cover types, such as spruce and fir, naturally develop a continuous canopy made up of multiple layers of shade tolerant species. Other types, such as lodgepole pine, tend to grow in dense, single-storied stands. The four canopy cover classes and associated vertical structures are described in Table 12.

Table 12. Forest density classes and associated vertical structures.

Tree Density Class	Canopy Cover Range	Description
Non-forested	<10%	Areas with less than 10% canopy cover are non-forested. This class may include open forest savannas or persistent grass and shrub communities that occur on the warm dry broad potential vegetation group. Such sites may have multiple age classes but large fire resistant and drought tolerant trees, such as Ponderosa pine, are favored. This class also includes areas on any potential vegetation type that have been recently de-forested through disturbance and trees have not yet re-established. Finally, true non-forested communities, such as grasslands, riparian and wetlands, and alpine communities, are included.
Low to Medium	10-39.9%	Low and medium tree canopy cover classes represent relatively open forests with 10 to 39.9% canopy cover. This class is common in young forests. In addition, low densities are found in dry forest types at all stages of succession, particularly in the warm dry broad potential vegetation group where site conditions or disturbances maintain low tree density. Cool moist or cold forests may also be in this condition, particularly in areas impacted by disturbances such as mountain pine beetle infestations.
Medium-High	40-59.9%	The medium to high tree canopy cover class represents a more fully stocked forest, a condition which is common in both warm moist and cool moist potential vegetation groups. Examples of forests with this density could include mature single-storied lodgepole pine or spruce and fir multi-storied stands. Dry forests may also be in this density class, particularly where fire has been excluded and understory layers have developed.
High	60%+	The high canopy cover class includes forests with a relatively closed canopy, most often on productive sites on the cool moist broad potential vegetation group. This density class is common in stands with a spruce and fir component in a multi-storied condition. This condition also arises in single-storied lodgepole pine and sometimes Douglas fir that regenerate to extremely high densities after fire. High tree density can limit tree growth and sunlight to the understory, limiting vegetation in the understory. This condition may also occur in dry forests that have missed natural fire entries and developed layers in the understory.

Data Source: (Barber et al. 2011).

Landscape Resilience

Resistance, defined as "the ease or difficulty of changing the [ecological] system," is one of the attributes of resilience (Walker et al. 2004). Holling (2001) says that resistance can be increased by increasing diversity. Both the dominance type and size class indicators are easily measured components of diversity on the landscape, which is a measure of resilience. Density is another important measure which can be used as an indicator of resilience and diversity at the landscape scale. For example, highly dense lodgepole pine stands are more susceptible to attack by mountain pine beetles (*Dendroctonus ponderosae*) than stands having low density. The distribution and extent of highly dense lodgepole pine stands will have an impact on the occurrence of mountain pine beetle disturbance events.

Insect and disease agents are a component of forest resiliency. The methodology developed to model the effects of insect and disease uses a weighted matrix of risk rating evaluations to assign an overall insect and disease risk rating across each potential vegetation type within each management area. The two primary insects include mountain pine beetle and Douglas fir beetle (*Dendroctonus pseudotsugae*). The disease risk rating is a composite of risk rating representing the major root disease pathogens found within north Idaho forests (Lockman et al. 2016, Holden et al. 2020).

Density is a factor in both fire behavior and fire effects resulting from wildland fire. Dense forested settings typically have greater amounts of vertical fuels, as well as surface fuel loading, which contributes to severe fire effects. Disturbance resulting from severe fire effects outside of the natural range of variation are not an indicator of a resilient system. Projected wildfire is used as a component of landscape resiliency to quantify differences between alternatives. Both density and size class are components of insect and disease hazard ratings. Insect and disease hazard ratings are expected to change because of changes in dominance type transitions. The extent and rate of change in dominance type transitions will differ by alternative.

Landscape patterns are developed by disturbance events at both the spatial and temporal scales. Management actions, as well as natural disturbance events, will determine the frequency and scale of openings in the forest canopy. Taken together, both projected wildfire and insect and disease hazard ratings determined for each management area and potential vegetation type group are predictive metrics that influence landscape patterns. Changes in projected wildfire and insect and disease hazard ratings resulting from differences in management intensity associated with each alternative will influence the extent and rate of change on the landscape pattern.

The methodology for developing plan components for old growth and for anticipating effects to old growth is discussed in detail in the "Old Growth Rationale" paper that is in the project record. The rational supporting plan components for old growth should reflect that the Nez Perce-Clearwater is considerably outside of the natural range of variation for dominance types and should incorporate thinking about forested vegetation, rather than simply restricting activities within all old growth. To do this, plan components discuss underrepresented resilient dominance types while allowing harvest within overrepresented and non-resilient dominance types.

Measurement Indicators

Land Management Plan direction must provide for ecological integrity while contributing to social and economic sustainability. To achieve this, desired conditions have been developed for key vegetation components. Desired conditions describe what would restore and maintain ecosystem integrity while contributing to social and economic sustainability. Though the Land Management Plan provides direction for a relatively short period of time, desired conditions were developed with the long-term view in mind due to the long-lived nature of tree species. To deal with the uncertainty in future conditions, desired conditions incorporate strategies that would maintain or improve the resilience of the ecosystem and promote sustainability and adaptability of vegetation. The desired conditions incorporate terrestrial and watershed restoration strategies to promote landscape scale resiliency.

The future will not be the same as the past. Therefore, in addition to the natural range of variation, additional factors were considered in the development of desired conditions. These included maintaining conditions that contribute to long-term resilience given uncertainties in future climate and disturbances; sustaining stand structures or species compositions that provide habitat for at-risk wildlife or plant species; conserving rare structures or components; existing or anticipated human use patterns; the effects changing climate may have; and ecosystem services expected from forest lands, such as the fuels reduction projects, production of forest products, and recreational opportunities.

The issue statement from scoping and public collaboration relative to forest vegetation is:

Desired conditions for forest vegetation should be met through natural processes or through active management. The rate of progress towards the desired conditions should occur at a faster or slower pace. Desired conditions should include higher compositions of early seral species and increased or decreased patch sizes and increased or decreased tree densities to meet ecological habitat needs of wildlife species, maintain resiliency of forest vegetation communities, and to meet social needs of forest users at a local, regional, and national scale.

Dominance types, size class distribution, and density were chosen as indicators of the extent to which each alternative maintains, improves, or restores ecological integrity. Landscape pattern, prevalence of aspen (*Populus tremuloides*), and old growth characteristics were chosen as indicators of resilience, ecological function, and diversity.

Dominance Types

Dominance types for the desired conditions are defined using the same definitions as the DOM_MID40 attribute in the Existing Vegetation Classification (Barber et al. 2011). This method uses a 40 percent plurality determined by trees per acre for seedling and sapling size and by basal area for all other sizes to determine the dominance type of a pixel. This means that a pixel receives the classification of the tree species that is most prevalent, and species must comprise at least 40 percent of the pixel.

Dominance type was chosen as an indicator because dominance type is one of the primary ways in which the landscape is departed from the natural range of variation (See SIMPPLLE Natural Range of Variation results). To analyze dominance types, the Hybrid 2015 dataset from the Forest Inventory and Analysis (FIA) database was used to generate estimates of dominance types using the Region 1 Summary Database Estimator. The Dominance Group Mid-40 was combined with the Dominance Group 6040 attribute to track minor species components. This attribute is based on a 60 percent threshold and a 40 percent threshold where a stand is classified as a given species if it comprises 60 percent of the stand, then if no species comprises 60 percent of a stand, it is classified by the species that comprises 40 percent of the stand (Barber et al. 2011). Estimates were generated as “final” in the estimator, which is recommended for planning (Bush et al. 2018). Because the exact effects of timber harvest and fire are unknown, plots that had been affected by fire and timber harvest since the time of sampling were removed. This means that all plots that had been burned or harvested after they were sampled were not included in the estimates of preliminary current conditions. Subsequently, plots affected by wildfires between 2015 and 2017 were re-measured and this updated data was included in the final estimates of current conditions. Disturbances are critically important for the development of successional pathways and vegetation patterns.

The effect each alternative would have on dominance types was originally analyzed using Spectrum and the modeling was performed by Kendrick Greer of Mason, Bruce, and Girard. A design document was written recording the various parameters used to predict dominance types under each alternative. This document is included in the project record. Transition pathways were created for Spectrum that identify the requirements for dominance types to change and are also part of the project record. As modeling development progressed, it was recognized that the Spectrum model was not robust enough to handle all the modeling elements and parameters needed to generate this comparative analysis. The original Spectrum design document and data input records were imported into the PRISM model to assure that the model could generate a solution for each parameter across all alternatives. All PRISM documentation is included in the project record.

Size Class

Size class was identified as a forestwide indicator. As above, the rationale for this is that size class distribution on the Nez Perce-Clearwater is departed from the natural range of variation (see SIMPPLLE Natural Range of Variation results). Size class distribution refers to the amount of the Nez Perce-Clearwater within different size classes rather than the geographic location of the size classes. Size classes are defined by basal area weighted average diameter, which is in accordance with and described in greater detail in the Region 1 Existing Vegetation Classification document (Barber et al. 2011). The analysis was performed using the Size Class National Technical Guide, which indicates that the size classes coincide with the size classes used in the guide.

The desired conditions, based on natural range of variation estimates, are partitioned by management area for the same reasons as above for dominance types. Because Management Area 3 has objectives for growing timber as a commodity, the size class distribution is adjusted to accommodate the need to maintain a balance of all size classes. Since much of Management Area 3 is suitable for timber production, it should be maintained with a size class distribution that supports a commercial harvest entry schedule. A small percentage of early seral grass-shrub size class is maintained to provide for wildlife habitat desired conditions and to reflect natural vegetation patterns at the landscape scale.

Size classes, as defined in this analysis, are broken into the same classes used in the Existing Vegetation Classification (Barber et al. 2011) and are defined using the same basal area weighted diameter methodology. While not specifically measured in a quantifiable way, the size class section also contains a discussion on expected effects to old growth from the alternatives because old growth was brought forward as an indicator during public involvement. Snags were also brought forward during public involvement. Although they are not used specifically as an indicator here, this section will include a discussion on snags.

Large and very large diameter live trees are commonly identified as key components of forested ecosystems across the Northern Region. Large trees are defined as those greater than or equal to 15 inches diameter at breast height (DBH) and very large trees are greater than or equal to 20 inches diameter at breast height. These trees, particularly long-lived fire tolerant species, represent important elements of ecosystem diversity whether they occur at low or high densities. Fire tolerant species can survive low to moderate intensity fire, providing seed sources and contributing to the recovery of the forest after disturbance, promoting resilience, and providing long-term structural diversity. Where present in sufficient numbers, they contribute to late successional forest and, in some cases, old growth. They provide important wildlife habitat, both as live trees and when they die, as snags and downed wood. Additionally, they can be of high economic value for wood products.

Resource specialists and members of the public are interested in the amount and distribution of large and very large trees occurring across the landscape. This understanding is important in the context of defining the natural range of variation, desired conditions, and resilience of forested ecosystems. The Northern Region Existing Vegetation Classification System (Barber et al. 2011) includes a size class metric, which classifies plots or stands based on the basal area weighted average diameter; a single label is assigned to a plot or stand. However, scattered individuals, groups, and clumps of large and very large trees may occur in forests classified into a smaller size class. To characterize stands or plots where large and very large trees occur at certain minimum densities, an attribute has been developed for analysis and monitoring in the Northern Region: Large-tree Structure. Large-tree Structure, coupled with Size Class, provides information on the density of large trees as well as the average size of the trees on a plot or within a stand. These attributes are related but refer to distinct resource information needs.

Dominance and size class were chosen as indicators because they are two of the key elements of forest vegetation that are most readily changed by management actions and natural disturbance events (Larson and Churchill 2012). They are also two ecosystem elements for which the natural range of variation information is available. These two elements have associated quantified desired conditions, so the effects of each alternative relative to meeting desired conditions for forest vegetation are readily measured, detected, and displayed. Dominance and size class are both measured by broad potential vegetation type and management area. These delineations were used because desired conditions vary by potential vegetation type and because the tools to affect dominance and size class vary by management area.

Forest Density

Density was selected as an indicator in response to public input and because forest density is departed from the natural range of variation. As with dominance types and size class distributions, density objectives will vary between potential vegetation type group and management area objectives.

Density was chosen as an indicator because density affects tree vigor (Long 1985, Hood et al. 2016) and also affects the ability of various tree species to retain dominance as with Douglas fir encroachment in Ponderosa pine stands. Density is readily quantified and displayed and is a measure of how each alternative would affect overall forest vigor and the extent to which some early seral dominance types are retained. It is also described in this analysis because it is a critical coarse filter element for wildlife in the warm dry potential vegetation type group. For this analysis, density is described by relative canopy cover in classes defined in the Existing Vegetation Classification (Barber et al. 2011). Density classes are defined by potential vegetation type group by management area.

Landscape Resilience

Resilience is used as an indicator to deal with several concerns raised during scoping and collaboration. The following quote was brought forward from scoping as an indicator:

The response of vegetation to disturbances and stressors — effects of the alternatives on the hazard of wildfire, key insects and diseases, weather disturbances, and climate change.

Resilience is also helpful in displaying differences between alternatives because it represents a sort of composite of other indicators. Resilience shows the extent to which vegetation is or is not likely to respond to various stressors. While the various elements of vegetation, such as dominance type or size class, show how a particular aspect of forest vegetation is trending toward desired conditions, resilience as an indicator provides management implications for those trends and the combination of the trends.

Measures used for resilience will vary slightly from those identified during scoping. The key measures of resilience used in this analysis are:

- Insect and disease hazard ratings
- Projected wildfire
- Landscape pattern

Resilience to climate change and weather disturbance were not specifically used as measures because these are largely related to dominance type and size class diversity (Halofsky, Peterson, et al. 2018a, b). Insect and disease hazard describe the potential implications of varying dominance types and size classes. Projected wildfire was used in this analysis in place of hazard from wildfire, which was a previously proposed measure. Fire is an important disturbance agent on the landscape of the Nez Perce-Clearwater; projected wildfire captures the importance of fire and identifies the risks associated with departure from the natural range of variation for wildfire frequency and severity type of fire that would have occurred historically. Landscape pattern is used as a qualitative measure of resilience because of the close tie between landscape pattern and landscape function (Turner et al. 2001, Hessburg et al. 2015).

In 2000, the President directed the Secretaries of Agriculture and the Interior to recommend how best to respond to severe wildland fires, reduce the impacts of fire on rural communities, and ensure sufficient firefighting capacity in the future. As a result, Congress directed development of the National Fire Plan, which precipitated LANDFIRE[12], along with the creation of a National Cohesive Wildland Fire Management Strategy (U.S. Department of Agriculture and U.S. Department of the Interior 2014b). The National Cohesive Wildland Fire Management Strategy deals with responses to wildfire, restoring and maintaining resilient landscapes and creating fire-adapted communities all based on a scientific foundation. LANDFIRE is a shared program between the United States Department of Agriculture Forest Service and United States Department of the Interior's wildland fire management bureaus under the direction of the Wildland Fire Leadership Council (WFLC). LANDFIRE produces a comprehensive, consistent, scientifically based suite of spatial layers and databases for the entire United States and territories.

LANDFIRE is used to classify vegetation according to the degree of departure from the natural range of variability associated with a given vegetation cover type. Forested vegetation types are described by fire regime in terms of the percentage of departure from the natural range of variation ranges. The projected amount of wildfire and fire frequency differs between fire regimes. Table 13 illustrates the fire regime classifications and departure percentages from historical fire occurrence.

Table 13. Fire regime departure expressed as percent departure of extent burned from Natural Range of Variation.

Fire Regime Group	Existing Average Acres Burned per Decade	Average Desired Acres Burned per Decade	Current Fire Regime % Departure	Desired Fire Return Interval (Frequency)	Desired Fire Severity
I	45,919	195,500	77%	0-35 years	Low to mixed
II	3,141	10,000	68%	0-35 years	High
III	89,579	305,500	71%	35-200 years	Mixed/low
IV	111,496	80,500	-38%	35-200 years	High

[12] LANDFIRE (LF), Landscape Fire and Resource Management Planning Tools, is a shared program between the wildland fire management programs of the U.S. Department of Agriculture Forest Service and U.S. Department of the Interior, providing landscape scale geo-spatial products to support cross-boundary planning, management, and operations.

Fire Regime Group	Existing Average Acres Burned per Decade	Average Desired Acres Burned per Decade	Current Fire Regime % Departure	Desired Fire Return Interval (Frequency)	Desired Fire Severity
V	2,423	850	-185%	200+ years	High to mixed to low
Total	252,558	592,350	57%	Regime dependent	Regime dependent

Data Source: Calculation_SRF_MF.xlsx.

The dominant, historical fire regime that occurred within forested vegetation in the northern Idaho region can be characterized as a variable or mixed-severity fire regime (Zack and Morgan 1994, Brown and Smith 2000). Severity refers to the amount of overstory vegetation replacement and the effect on dominant vegetation cover types; in fire management, severity is "defined as the amount of vegetation replacement, and its effects to the dominant vegetation (Barrett et al. 2010)." This type of fire regime commonly had a moderately short fire-return interval for nonlethal or mixed severity fires with lethal crown fires occurring less often. Relative to the other two common fire regimes that are often recognized for forested vegetation—the nonlethal and stand-replacement regimes—the mixed-severity fire regimes are the most complex (Agee 2005). Individual mixed-severity fires typically leave a patchy pattern of mortality on the landscape, which creates highly diverse communities. These fires kill a large percentage of the more fire-susceptible tree species, such as hemlock, grand fir, subalpine fir, and lodgepole pine, and a smaller proportion of the fire-resistant species, including Western larch, Ponderosa pine, whitebark pine, and Western white pine (Arno et al. 2000).

Aspen is a rare and unique habitat element on the Nez Perce-Clearwater, and, as such, is important for the diversity it provides and is an important coarse scale feature for wildlife (Rogers et al. 2014). It was chosen as an indicator because one of the ways in which the alternatives vary is the extent to which aspen is increased on the landscape through disturbance processes. The amount of aspen can be quantified; therefore, the extent to which each alternative meets the desired conditions for aspen can be readily analyzed and displayed.

Old growth characteristics were identified as a resource of concern during public scoping and as a critical component of ecosystem diversity and as a habitat element for species that require large diameter trees for part of their life cycle. Plan components discuss within-stand characteristics for each broad potential vegetation group, including the need to maintain legacy trees to meet habitat needs for cavity nesting wildlife. Old growth was chosen as an indicator because the frequency and distribution of stands exhibiting old growth characteristics is expected to vary by management area and broad potential vegetation group because of proposed forest management practices and because of natural disturbances. Old growth is discussed in qualitative terms to compare how each alternative may influence the relative frequency and distribution of old growth components as compared to the No Action Alternative. In addition, large-tree structure is discussed to distinguish between those large trees, which contribute to diversity of stand structure within stands of all size classes and those trees which contribute to old growth characteristics.

Old growth is a structural condition that may exist during the late successional stage of forest development. Old growth provides wildlife habitat, biological diversity, and other ecosystem functions, such as carbon storage. It also contains seed sources that contribute to landscape resilience. The concept of old growth involves not only tree age but also characteristics, such as trees size and spacing, large dead standing and fallen trees, broken and deformed tops, bole and root rot, multiple canopy layers, canopy gaps and understory patchiness, cessation in height growth of oldest trees, near zero net productivity, and biochemistry of secondary metabolic products in old trees (Johnson et al. 1995). This condition is not static and, as old growth dies, it is replaced by younger forests as they age; therefore, the distribution of old growth across the landscape changes over time. The Nez Perce-Clearwater uses structural attributes to define old growth based on the best available scientific information (Green et al. 1992).

The Forest Inventory and Analysis (FIA) program is mandated by congress to provide a comprehensive, continuous, and statistically sound field inventory of national forest resources and National Forest System lands. FIA is administered by the Research and Development branch of the Forest Service (Bush et al. 2006). The FIA mission was first defined in The McSweeney-McNary Forest Research Act of 1928 to generate a comprehensive inventory and analysis of renewable resources of the United States. The Forest and Rangeland Renewable Resources Planning Act of 1974, P.L. 93-378, as amended, directed the Secretary of Agriculture to prepare a Renewable Resources Assessment every 10 years, which utilizes data trends derived from FIA data. Congress has further mandated through The Agricultural Research, Extension, and Education Reform Act of 1998 (P.L. 105-185) that FIA data be consistently collected and summarized across all land ownerships, including public lands managed by the National Forest System, with reports for each state produced at five-year intervals. The integrity of FIA sample locations is protected to assure that they remain representative of unsampled locations. In compliance with Public Law 106-113 (Fiscal Year 2000 Consolidated Appropriations Bill), FIA closely restricts disclosure of exact coordinates for all FIA sample locations, including those on public lands. This protects FIA sample locations from unauthorized access and unintentional impacts or improper tampering. For this reason, it is not permissible to render a spatial distribution of old growth forest locations on the forest based on FIA data. FIA currently uses a standardized configuration for its sample locations in the field. This configuration is designed to measure a diverse spectrum of forest metrics from species, size and age classes, forest density, and structure across all land types and within public and private ownerships. The National Forest System applies its definition of old growth forest using data collected according to FIA standards and maintained in the FIA database (Czaplewski 2004).

The Nez Perce-Clearwater National Forest is covered by 669 FIA sample locations (Bush and Reyes 2020). The FIA sampling grid provides an equal probability sample of each national forest. This sampling grid uniformly covers Wilderness Areas and roadless areas as well as lands managed for other purposes, regardless of their suitability for timber production. Therefore, the FIA sampling frame is appropriate to make scientifically defensible and reliable inferences regarding the condition of forests within sufficiently large areas, regardless of their management regime. These inferences include estimation of snag density and the proportion of all forested areas in a national forest that meets its definition of old growth forest (Czaplewski 2004).

To conduct analysis of forest attributes over large areas such as the 3,939,057 acres of the Nez Perce-Clearwater, it is infeasible to maintain an inventory of all vegetation on every acre. FIA provides a statistically-sound representative sample designed to provide unbiased estimates of forest attributes. This inventory design is appropriate for making estimates of a variety of attributes of forested lands across large landscapes such as National Forests, multiple fifth-code watersheds, and ecological section. The FIA sampling frame uniformly covers all forested lands, regardless of management emphasis. Therefore, wilderness areas (Management Area 1), roadless areas (Management Area 2), and actively managed lands (Management Area 3) all have the same probability of being sampled. FIA data comes from a spatially balanced statistical sample that allows estimates of means and their associated standard errors and confidence interval accuracies (Bush et al. 2006).

Carbon stocks were brought forward as an indicator during public involvement and are discussed in the Climate Change and Forest Carbon section.

Affected Environment

Existing Condition

A primary goal of the Land Management Plan action alternatives is to provide for ecological integrity and sustainability, supporting the full suite of native plant and animal species while providing for the social and economic needs of people. Resistance and resilience are important concepts applied at both the stand and landscape level. At the stand level, resistance and resilience are important factors to consider in the development of forest management implementation guidance. The landscape scale is integral in monitoring for attainment of desired conditions for ecological integrity and sustainability. Resistance at the stand level refers to the influence of structure and composition on disturbance severity while the landscape level refers to the influence of structure and composition on the spread of disturbance. Resilience at the stand level refers to the influence of disturbance on subsequent structure and composition and at the landscape level as the influence of disturbance on subsequent forest structure and composition (DeRose and Long 2014).

This section begins by describing the primary ecosystem and ecosystem processes and disturbances, then discusses vegetation composition and structure. Composition is the type and variety of the vegetation while structure is the physical form of vegetation, such as the vertical and horizontal arrangement of plants. Forest structure is complex, but this analysis is coarse, relying on classifications of forest size class and density. Separate sections discuss more specific elements of structure, including snags, downed wood, and old growth. Finally, landscape pattern is discussed. Landscape pattern can include a nearly infinite number of attributes; for this analysis, however, the focus is on early successional forests.

Abiotic Ecosystem

Climate and Ecological Provinces

The overall ecological context for the northern Rocky Mountain forests is the interaction of effective water availability and disturbance processes and the pattern of vegetation resulting from those interactions. In the western portion of the northern Rocky Mountains, which includes northern Idaho, the warmer Pacific maritime air mass dominates producing upwards of 30 to 40 inches of precipitation each year, on average. Averages for precipitation vary greatly across the forest. The northern portion of the forest, north of the North Fork River, can experience years with 60 to 80 inches of precipitation, while the southern portion of the forest along the Salmon River may average only 20 inches. This variation in precipitation patterns across the forest gives rise to differences in species composition and site productivity. Air masses can also move across this region from the southwest, crossing California and Nevada, and bringing little moisture but bringing dry thunderstorms when they hit the mountains and valleys of southern and central Idaho. One such storm can release over 80,000 lightning strikes. Also, dry cold air masses are sometimes pulled out of north-central Canada, bringing high winds, very dry air, and very cold temperatures in the winter.

This climate context, combined with soils, defines where different forest types can occur. The soils part of the equation is best understood by looking at the National Hierarchy of Ecological Units, where Provinces are at the largest scale, further subdivided into Sections at the scale of national forest size, and, ultimately, Subsections (Nesser et al. 1997). Subsections were developed by further subdividing Sections. For forest planning, Biophysical Settings were developed that are approximately equivalent to the Subsections in scale and roughly approximate the boundaries of the Subsections but were developed from aggregating land types to provide a picture of lands with very similar topography, water balances, growing seasons, and forest types.

The Nez Perce-Clearwater is almost entirely within two ecological Provinces as delineated by Bailey (1994):

M333: The Northern Rocky Mountain Forest Steppe—Coniferous Forest—Alpine Meadow Province, located north of the Middle Fork Clearwater and Lochsa Rivers

M332: The Middle Rocky Mountain Steppe—Coniferous Forest—Alpine Meadow Province, located south of the Middle Fork and Lochsa Rivers.

The Northern Rocky Mountain Forest Steppe province extends from east of the Cascade Mountains in Washington to the Continental Divide in Montana, into Canada to the north, and throughout northern Idaho. The Middle Rocky Mountain Steppe province extends over the Blue Mountains in northeastern Oregon, the Salmon Mountains in central Idaho, and into the basins and ranges of southwestern Montana. Most of these two provinces have been glaciated with landforms typical of this process.

Two ecological sections (McNab et al. 2007) within these provinces dominate the Nez Perce-Clearwater: the Idaho Batholith (M332A) and Bitterroot Mountains (M333D). Small pieces of sections 331A (Palouse) and M332G (Seven Devils area) also occur within the Nez Perce-Clearwater. However, these two sections have narrow extents and are similar enough to the adjacent sections that, for forest planning purposes, they have been combined with the adjacent Sections—Palouse with the Bitterroot Mountains and Seven Devils with the Idaho Batholith. See the 'Ecological Sustainability Summary' section for further detail.

Ecosystem Processes and Disturbances

Vegetation is not static; it is constantly changing across space and time due to drivers such as climate, succession, fire, insects, and diseases. The complex interactions between these processes over past centuries resulted in the vegetation that currently exists and will influence changes into the future. Since the late 1990s, national disturbance rates have been influenced primarily by natural disturbances rather than anthropogenic ones and increasing rates for forest decline have been concentrated in the western United States where extended droughts have coupled with increasingly high temperatures to create increasingly stressed and vulnerable forests (Cohen et al. 2016, Mildrexler et al. 2016).

Climate

Climate strongly influences vegetation and ecosystem processes. Temperature and moisture patterns dictate what plants can establish and grow on a site and influence factors such as growth rates and density. Drought can alter vegetation directly by killing plants or indirectly by increasing the frequency and severity of disturbances or rendering forests more susceptible to insect and disease. Over geologic time, changes in climate are natural; even so, because of climate change, forests may face rapid alterations in the timing, intensity, frequency, and extent of disturbances (Dale et al. 2001).

Considerable natural variation in climate has occurred historically. Future climate projections suggest that temperature increases will exceed the historical variation for average monthly maximum temperature. Specific changes in ecosystem components due to expected climate change are difficult to predict and are highly uncertain, especially in the diverse terrain of the northern Rocky Mountain region.

In the western United States, it is likely that water balance and disturbance dynamics will be more important than actual increased temperature in affecting vegetation. Longer, warmer growing seasons may increase growth rates; however, greater soil water deficits and increased evapotranspiration in the summer may offset this and increase plant stress. Growing sites on the Nez Perce-Clearwater are highly variable and are influenced by topographic position, aspect, and elevation. At any given time under variable climatic regimes, lower elevation forest cover types, such as Ponderosa pine, are drier than higher elevation cover types, such as subalpine fir. Drought conditions or effects of warm, dry climatic periods generally result in slower growth and decrease the ability of a site to support vegetation compared to cool, moist periods across all elevational gradients. Competition-based mortality increases during dry periods. Stress can also lead to higher mortality rates indirectly through susceptibility to insects or disease. Increasing soil water deficits can cause eventual shifts in species presence across the landscape as they become less able to regenerate or survive. Species located on sites at the margin of their optimal range would be most vulnerable. Species extent and distribution would be consequently impacted.

Climate changes are also expected to affect disturbances. There is a high degree of uncertainty associated with extrapolation of these effects to local sites. Persistent and recurring drought combined with high temperatures may give rise to "mega disturbances" in some areas that may cause tree mortality of a spatial extent, severity, and frequency surpassing that recorded during recent human history (Millar and Stephenson 2015). Studies of potential effects of climate change on fire and insect and disease suggest the following may occur across the western United States (Halofsky, Peterson, et al. 2018a, b):

Longer fire seasons, more days of high fire danger, increased frequency of ignitions, more frequent large fires, more episodes of extreme fire behavior, and increased average annual area burned.

Given availability and spatial distribution of host species, there may be elevated levels of native insects and disease. Predicted increases in temperature and drought will probably serve to increase pathogen populations in the future because they are able to migrate to new environments at a faster rate than trees.

Biotic Ecosystem - Vegetative succession

The Nez Perce-Clearwater has a wide diversity of terrestrial vegetation communities due to its geographic location, geology, topography, range in elevation, and climate. Vegetation ranges from dense coniferous forests in warm, moist, or dry valley bottoms to sparsely forested types on cold, steep, high-elevation sites. These vegetation communities also change over time. Simply stated, vegetative succession is the gradual replacing of one vegetation community with another. It is the basic ecological process of change in the composition, structure, and function of plant communities over time. It is based on the concept that every species has a particular set of environmental conditions under which it will reproduce and grow optimally. If these conditions remain relatively constant, the species will flourish. However, species have impacts on their own environments and on each other, and this is one factor that causes the plant community to change over time. External factors, such as weather and disturbance events to include fire and disease, also cause change in plant communities.

The successional process follows a pathway with each major step along the way referred to as a seral or successional stage. In a simplified model for a coniferous forest in the northern Rocky Mountain ecosystem, early successional stages typically follow a disturbance, such as fire, which kills all or a portion of the existing trees and other plants while leaving the physical environment intact. Trees and other plant species immediately start colonizing the site through a variety of reproductive methods, such as seeds or sprouting from underground roots and rapidly fill up all available growing space. Then follows a series of intermediate successional stages typically from about 40 to 140 years after the disturbance, collectively referred to as mid successional stages, where plant species are well established, trees grow larger, and forests grow denser. Changes in environmental conditions and competition for limited resources, mainly water and sunlight, cause some species to decline or disappear and others to expand. Forest structure may become more complex; for example, complexity can be created by greater variations in the tree height canopy layer or increased accumulation of snags and downed woody material from dying trees. Ultimately, the stand develops into a late successional stage, typically 150 or more years after the disturbance, depending on the site. As compared to mid-successional stages, the forest structure is usually more complex, tree diameters and heights are larger, and shade tolerant grass, forb, shrubs, and trees predominate. In the classical model of succession, this stage would be considered the culmination of the successional process and is called the climax forest community. The climax forest represents a state of relative stability in forest composition, structure, and function, with all existing species able to perpetuate themselves within the forest without catastrophic disturbance.

Of course, this description of successional stages and associated forest characteristics is an oversimplification of what is a far more complex and tangled web of inter-relationships between site conditions, vegetation, and the ecosystem drivers and stressors. Highly diverse forest conditions can occur within any one successional stage and age. Time spent within a stage varies and transition between stages is often gradual, except in the case of a stand-replacing disturbance that initiates the early successional stage. The abiotic conditions of a site, such as soils, aspect, and climate, and disturbance types and patterns are key to understanding the different vegetation communities that may occupy the site and their characteristics over time. Classifying and mapping of the landscape into potential groups of vegetation types is a common and useful way of describing successional pathways and the vegetation communities that may exist across the landscape both temporally and spatially. Refer to the Measurement Indicators section for a description of the potential vegetation types.

Tree species are often distinguished as playing either an early or late climax successional role. Species that have traits that enable rapid colonization and domination of a site after a major disturbance, such as fire, are called early successional. They are typically the less shade tolerant species that characteristically flourish only under conditions of full or nearly full sunlight and have rapid, early height growth. Western larch, Ponderosa pine, lodgepole pine, Western white pine, and whitebark pine are the major conifer early successional species on the Nez Perce-Clearwater. Both aspen and birch are examples of early successional hardwood species. Late successional, or climax, species are typically the most shade tolerant species capable of reproducing and growing to maturity in dense forest conditions. Grand fir, cedar, spruce, hemlock, and subalpine fir are climax species on the forest. Douglas fir functions prominently as both an early and late successional climax species, depending on site conditions. In fact, most species can play multiple successional roles and successfully occupy stands in early or later successional stages.

An important feature to note about the forests of the northern Rocky Mountain ecosystem is the influence of long-lived, fire tolerant, early successional species in the successional process and in the composition and structure of forests at all stages of development and on all sites. Species such as Western larch, Ponderosa pine, Western white pine, whitebark pine, and Douglas fir can survive for several centuries. In many areas, the fully developed “true” climax forest conditions may be relatively uncommon due to the long-term persistence of these early successional species. These species’ tolerance of low or even moderate severity fire allows some to survive through the less severe fire events. Though they may or may not be numerous, they grow to large stature and become prominent features of the overstory tree canopy, providing important structural components of late successional and old growth forests. When severe stand replacing fire occurs, they are well adapted to take advantage of the open burned forest conditions and reforest the site. In non-forested communities, early seral plants include grasses or forbs that re-sprout quickly, such as Idaho fescue. Later sections of this analysis discuss forest size and structure classes, old growth, and dead trees, which highlight this feature of Nez Perce-Clearwater ecosystems.

Successional pathways are complex, and the rate of change can be variable; simplification of the process is necessary for analysis. The evaluation of forest size classes provides the means to evaluate successional change of forests over time. The early successional stage is characterized by the seedling and sapling size class. As trees grow, they transition from smaller size classes into larger size classes. Mid-successional forests are associated primarily with the small and medium forest size classes, but forests in the large size class are also mid-successional, depending on tree ages and species, in some cases. Late successional forests are associated mainly with the large and very large forest size class.

Disturbance

Fire Regimes and Potential Vegetation Types

To better understand the fire frequency disturbance processes, the classification of natural fire regimes is usually defined in a historical sense, typically restricted to the pre-1900s, but are natural in the sense of incorporating effects of indigenous cultures. The human component of natural fire regimes cannot be separated out in most cases. A fire regime describes the frequency, predictability, and severity of fire in an ecosystem. The LANDFIRE classification found in Table 14 is a generalized system that defines the five natural fire regime groups based on the average number of years between fires known as fire frequency, combined with characteristic fire severity reflecting percent replacement of dominant overstory vegetation (U.S. Department of Agriculture 2010c).

Table 14. LANDFIRE fire regime groups frequency, severity, and severity description.

Fire Regime Groups	Frequency	Severity	Severity Description
I	0–35 years	Low to mixed	Generally low-severity fires replacing less than 25% of the dominant overstory vegetation; can include mixed-severity fires that replace up to 75% of the overstory.
II	0–35 years	Replacement	High-severity fires replacing greater than 75% of the dominant overstory vegetation
III	35–200 years	Mixed to low	Generally mixed severity; can also include low severity fires
IV	35–200 years	Replacement	High-severity fires
V	200+ years	Replacement or any severity	Generally, replacement severity; can include any severity type in this frequency range

Note: Fire Regime Groups 111, 112, 120, 121, 131, 132, and 133 are non-burnable.

Data Source: Interagency Fire Regime Condition Class (FRCC) Guidebook version 3.0, September 2010 (U.S. Department of Agriculture 2010c)

The combination of fire regime groups and potential vegetation types are used to describe the historic disturbance interaction of wildfire and vegetation. Fire Regime Groups I and III define a wildfire disturbance regime across those forested and non-forested vegetation types that adapted to frequencies of low, high, and mixed severity fire. Within the dry Ponderosa pine and Douglas fir vegetation types or warm dry potential vegetation type, frequent low and mixed severity fires kept the stands open with bunchgrass in the understory and thinned many of the smaller trees (Arno 1980). In the non-forested vegetation types, grasslands were often maintained as result of frequent fires set by both lightning and aboriginal fire (Barrett 1982).

Historically, a high percentage of the forested and non-forested vegetation types was also influenced by mixed severity fire regimes. Fire Regime Group III created a mosaic of Douglas fir, Western larch, grand fir, and western hemlock vegetation types that resulted in heterogeneous successional patterns on the Nez Perce-Clearwater. Fire Regime Group III is the most prevalent in all the forested broad potential vegetation types, as illustrated in Table 15.

Table 15. Acres of broad potential vegetation type group by primary fire regime, acres, and proportion of total acres.

Broad Potential Vegetation Type	Primary Fire Regime Group(s) Represented	Approximate Acres	Proportion
Warm Dry	I, III	873,295	22%
Warm Moist	III	1,503,725	38%
Cool Moist	III, IV	910,380	23%
Cold	IV	476,750	12%
Non-Forested	I, II, III, IV	172,690	4%

Data Source: GIS.

Landscapes with long return fire frequencies, generally over 100 years, were dominated by high severity, stand-replacement fire regimes. Fire Regime Groups IV and V represent the highest percent of the forested vegetation types with lodgepole pine as a dominant overstory species and cool moist sites where Engelmann spruce and subalpine fir are the climax species (Smith and Fischer 1997, Fischer and Bradley 1987).

Fire Regimes and Severity Acres

Fire frequency and severity contributes to changes associated with patch sizes or openings that are created when a fire burns through a given vegetation type. This also defines or shifts the structure of vegetation because of site productivity and succession. For example, large fires with small patches of regeneration are found in low severity fire regimes. Most of these patches are a result of mature large trees that survived wildfires and insects. Such patches are maintained as a fire resilient landscape through frequent low severity fires. The mixed severity fire regime created large patch sizes defined by varied stand structures. Specifically, low severity fire that had little mortality created larger tree size classes, while mixed severity fire created a multi-aged structure and those areas that burned with higher severity created more even aged structure. High severity fire regimes are driven by long fire return intervals and generally have higher severity on the vegetation, resulting in large patch sizes with late successional vegetation being burned (Agee 1998).

Fire Regime Departures and Resilience

Fire regimes are defined as characteristics of fire, such as the intensity, frequency, season, size, and extent that create fire effects for a given biophysical setting. Fire regimes can be altered by fire exclusion and land management practices. Only a small fraction of the pre-1900 annual average fire acreage is being burned today; when wildfires do occur on fire-excluded landscapes, they are likely to be more extreme in behavior, more severe, and with greater aerial extent compared to those occurring prior to the exclusion era (Finney 2003, Keane et al. 2002). Because of fire exclusion, landscapes tend to become more homogeneous with succession creating conditions that support more shade tolerant species. The distribution of patches changes over time creating less fragmentation, lower patch density and diversity, and larger patch sizes (Keane et al. 2002). For example, the alteration of fire regimes by fire exclusion has been greatest in dry forests, primarily those dominated by Ponderosa pine and Douglas fir (Graham et al. 2004). Figure 2 describes some the biophysical and human causes of fire regime change over time (Laris 2013).

Vegetation Departure

The disturbance regimes throughout the forest are dynamic and require a better understanding of change agents within each of the vegetation types to deal with the ecological departure from historical reference conditions. A standardized approach using projected wildfire compares existing vegetation composition for each biophysical setting to previously modeled reference conditions for those types. Specifically, departure from frequency and type of wildfire is a measure of departure from reference ecological conditions, whether pre-settlement or natural or historical, that typically result in alterations of native ecosystem. By using fire regimes as a proxy for reference conditions, the ecological departure from the natural fire regimes for each of the broad potential vegetation types across the Nez Perce-Clearwater is determined by projected wildfire (U.S. Department of Agriculture 2010c). For landscapes that were moderately or severely departed, those acres can provide the foundation for how many acres potentially need restoration.

The ecosystem components, such as species composition, structural stage, stand age, canopy closure, and fuel loadings, are representative of the resilience of potential vegetation types to current and future disturbance. With fire exclusion, dense understories and thickets of conifers have produced stands that are highly susceptible to a variety of insect and disease epidemics and severe wildfires. The fire regimes within the warm dry and warm moist potential vegetation type have moderate to high departures, indicating that many of these areas have missed one or more fire return intervals and have the potential for higher severity fire as a result. The cool and cool moist potential vegetation types have low to moderate departure but could move toward a higher departure without continued disturbance. Lastly, most of the shrub species are within their historical conditions. Table 16 displays the percent of projected wildfire occurring within each of the potential vegetation types across the Nez Perce-Clearwater. The warm dry and warm moist broad potential vegetation types are dominated by Fire Regime III, and the cool moist and cold broad potential vegetation types are dominated by Fire Regime IV. As discussed in previous sections, Fire Regime III is highly departed from the natural range of variation. Recent fires between 2015 and 2017 affected the cool moist and cold broad potential vegetation types, which reduced the departure of Fire Regime IV.

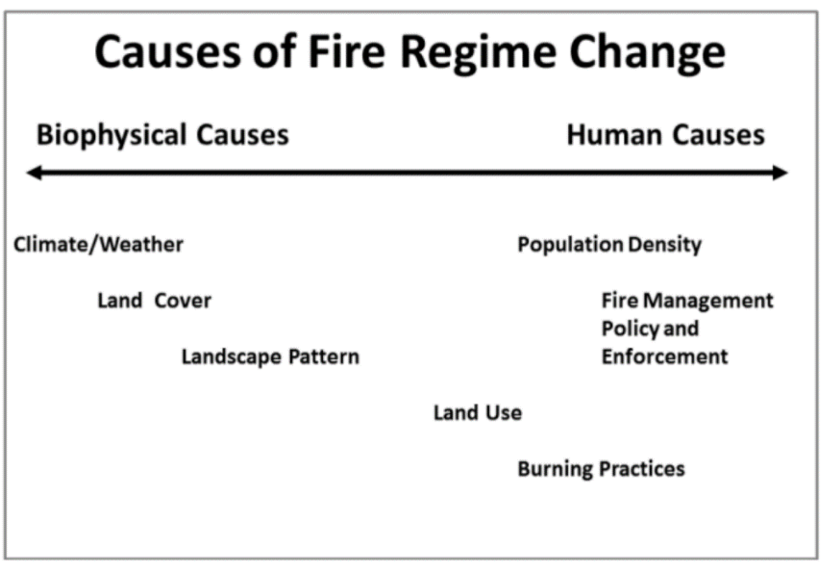

Figure 2. Biophysical and human causes of fire regime change over time.

Table 16. Acres of fire regime group (FRG) within each broad potential vegetation type.

Broad Potential Vegetation Type	Non-Burnable	FGR I	FRG II	FRG III	FRG IV	FRG V	Total Acres
Warm Dry	1.028	210,921	9,084	494,551	148,655	9,056	873,295

Broad Potential Vegetation Type	Non-Burnable	FGR I	FRG II	FRG III	FRG IV	FRG V	Total Acres
(% FRG)	(0%)	(24%)	(1%)	(57%)	(17%)	(1%)	(100%)
Warm Moist (% FRG)	1,426 (0%)	117,274 (24%)	1,271 (1%)	1,239,227 (82%)	124,524 (8%)	20,002 (1%)	1,503,725 (100%)
Cool Moist (% FRG)	712 (0%)	18,108 (2%)	183 (0%)	254,658 (28%)	635,103 (70%)	1,616 (0%)	910,380 (100%)
Cold (% FRG)	559 (0%)	9,466 (2%)	73 (0%)	109,467 (23%)	355,681 (75%)	1,504 (0%)	476,750 (100%)
Non-forested (% FRG)	6,631 (4%)	16,092 (4%)	6,969 (9%)	75,663 (44%)	66,133 (38%)	1,203 (1%)	172,690 (100%)

Wildfire

Fire is a primary ecological process that has created, maintained, and renewed vegetation on the Nez Perce-Clearwater. Fire fulfills many ecological functions, including carbon and nutrient recycling, snag and tree cavity creation, and stimulating seeding and sprouting of vegetation. Natural fire regimes include low, mixed, and high severity fires. The natural range of variation analysis showed that sites in the warm dry broad potential vegetation group tended to burn with mixed or low severity. The warm moist group burned with predominately mixed severity and the cool moist group tended to burn with stand replacing severity. All fire types were well represented in the cold broad potential vegetation group. See the Fire Management section for more information.

Forest Insects and Diseases

There are many insects and diseases that affect forest vegetation. Most are native and usually exist at low population levels. Some insects can cause dramatic effects but more often changes occur gradually. Insects and diseases that currently have the most notable impacts on the Nez Perce-Clearwater are discussed in this section. Refer to the Assessment (Halofsky, Peterson, et al. 2018a, b) for additional information.

Aerial Detection Survey (ADS) data from 2013 indicates that Douglas fir beetle (*Dendroctonus pseudotsugae*), fir engraver (*Scolytus ventralis*), spruce beetle (*Dendroctonus rufipennis*), Western spruce budworm (*Choristoneura occidentalis*), balsam wooly adelgid (*Adelges piceae*), and mountain pine beetle (*Dendroctonus ponderosae*) are causing damage across the Nez Perce-Clearwater. Though damage from other insects and diseases was not specifically observed, it can be assumed that other forest insects indigenous to the Inland Northwest occur at endemic levels within the project area and that other forest diseases are also present in the area.

Bark Beetles: Three primary bark beetles native to the Nez Perce-Clearwater are the mountain pine beetle, western pine beetle, and the Douglas fir beetle. Of these, the mountain pine beetle and Douglas fir beetle are having the greatest impact across the Nez Perce-Clearwater. Warming temperatures have directly influenced bark beetle-caused mortality, and climate changes are likely to have an effect (Halofsky, Peterson, et al. 2018a, b). Beetle populations may be favored by warm temperatures due to increased survival of beetles, increased numbers of generation in a year, and increased stress of host species. Future bark beetle-caused mortality will depend not only on the spatial distribution of host trees but also the ability of beetle populations to adapt to changing conditions.

Beetle outbreaks can lead to changes in fire behavior (Jenkins et al. 2008, Hansen et al. 2015). The changes to fire behavior vary in post-outbreak stands depending upon when they occur, the net result is a substantial change in species composition, and a highly altered fuels complex. The amount of fine surface fuels increases early in epidemics, while in post-epidemic stands, large, dead, woody fuels and live surface fuels dominate. For surface fires, both the rate of spread and fireline intensity are higher in epidemic stands. Passive crown fires are more likely in post-epidemic stands, but active crown fires are less likely due to decreased aerial fuel continuity (Jenkins et al. 2008). Increasing infestation severity may cause shifts from surface fire to passive crown fire under severe weather conditions (Hansen et al. 2015). Once dead trees fall to the forest floor, they create woody debris that can burn for long durations. The potential for crown fire during this stage would be dependent upon the remnants of other species in the stand. Other studies have shown varying results, and a review of literature indicates that the effect of mountain pine beetle infestations on fire occurrence and severity in lodgepole pine forests are unclear, and outbreaks in other forest types are unknown or need more research (Simard et al. 2008).

The natural range of variation analysis compared the average acres infested per decade with recent acres infested from 2008 to 2014. Mountain pine beetle infestation was well above the natural range, while Douglas fir beetle was at the lower end. Insect events are expected to be cyclic in nature with a wide range of variability. Severe bark beetle activity was at the high end of the natural range during warm and dry periods.

Mountain pine beetle is the most aggressive and persistent native bark beetle on the Nez Perce-Clearwater. Host species include lodgepole pine, Ponderosa pine, whitebark pine, and occasionally Western white pine. Lodgepole pine is the most abundant and widespread host species and tends to grow in large often nearly pure stands of similar size trees. This contributes to epidemic populations periodically developing, killing large numbers of trees, and spreading into surrounding forests of other host species. Severe beetle outbreaks can provide regeneration opportunities for shade intolerant tree species or allow the release of understory shade-tolerant tree species. Because regeneration is more episodic in Ponderosa pine than lodgepole pine, Ponderosa pine ecosystems may be less resilient to infestations (Briggs et al. 2015). In all forest types affected by mountain pine beetle, tree mortality increases the quantity of snags and downed woody material over time (Mitchell and Preisler 1998, Hansen et al. 2015).

Mountain pine beetle hazard ratings indicate the degree of vegetation susceptibility to insect attack. Hazard represents how conducive the vegetation is to the disturbance agent (in this case, mountain pine beetle), the expected severity of damage if the insect is present and is a function of forest conditions. Elevation, age, size, proportion, and density of host pine species are factors used in the hazard rating; separate ratings are generated for lodgepole pine versus Ponderosa pine (Randall et al. 2019). Although Western white pine may also be affected, no hazard rating is available. In the following figures, the sum of proportions of each analysis area does not necessarily equal 100 percent because plots that have changed due to fire or harvest are excluded from the estimates. Figure 3 displays the existing mountain pine beetle hazard in Ponderosa pine across the Nez Perce-Clearwater by broad potential vegetation group in each management area.

The warm dry potential vegetation type group has the largest percentage (5–10 percent) of area with high beetle hazard ratings. This is indicative of the species mix associated with the warm dry potential vegetation type group. Ponderosa pine is the most affected species by mountain pine beetle within the warm dry potential vegetation type group. Similar percentages of the warm dry potential vegetation type group have medium beetle risk hazard rating. The majority of the remaining potential vegetation type groups have low to moderate beetle hazard ratings.

Lodgepole pine occurs across all potential vegetation type groups but has the greatest abundance within the cold and cool moist potential vegetation type groups. Within the cold and cool moist potential vegetation type groups, mountain pine beetle averages over 15 percent and 10 percent, respectively (Figure 4). Moderate hazard ranges from 5 percent in the warm moist potential vegetation type group in Management Area 3 to over 30 percent in the cold potential vegetation type group in Management Area 3. Low hazard ratings are primarily associated with cool moist, warm moist, and warm dry potential vegetation type groups where lodgepole pine is less prevalent.

The mountain pine beetle hazard for whitebark pine is illustrated in Figure 5. Whitebark pine forests occupy the higher elevation zones within the cold and cool moist broad potential vegetation types. Over the last two decades, the mountain pine beetle has played an increasing role in whitebark pine mortality. As white pine blister rust affects a greater proportion of the whitebark pine population, trees weakened by this disease become increasingly susceptible to the mountain pine beetle. Warmer temperatures, such as potentially driven by climate change, may also play a role in creating a more favorable environment for the beetle.

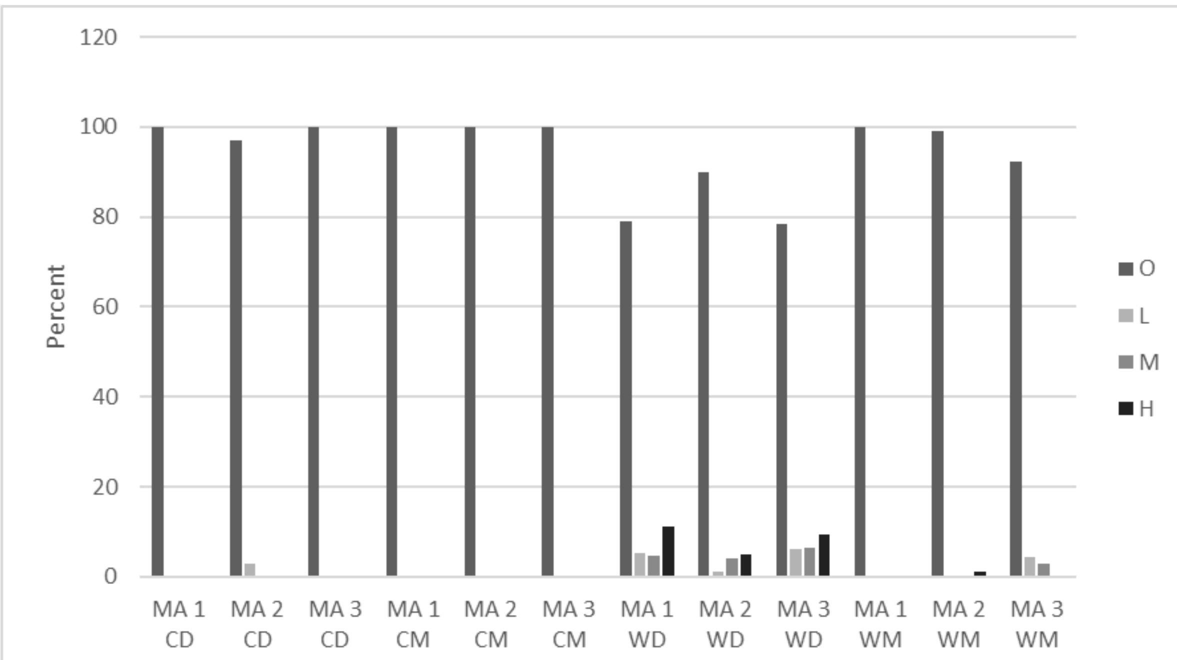

Figure 3. Percent Mountain pine beetle hazard rating for ponderosa pine by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015.

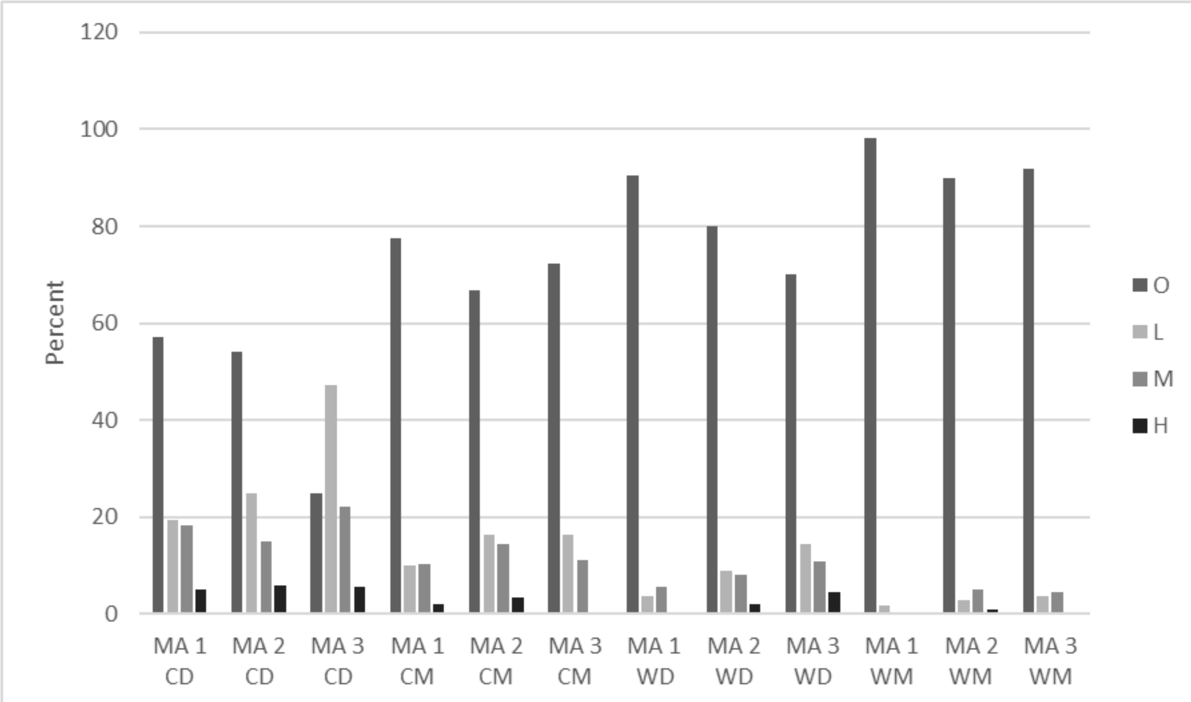

Figure 4. Percent Mountain pine beetle hazard rating for lodgepole pine by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015.

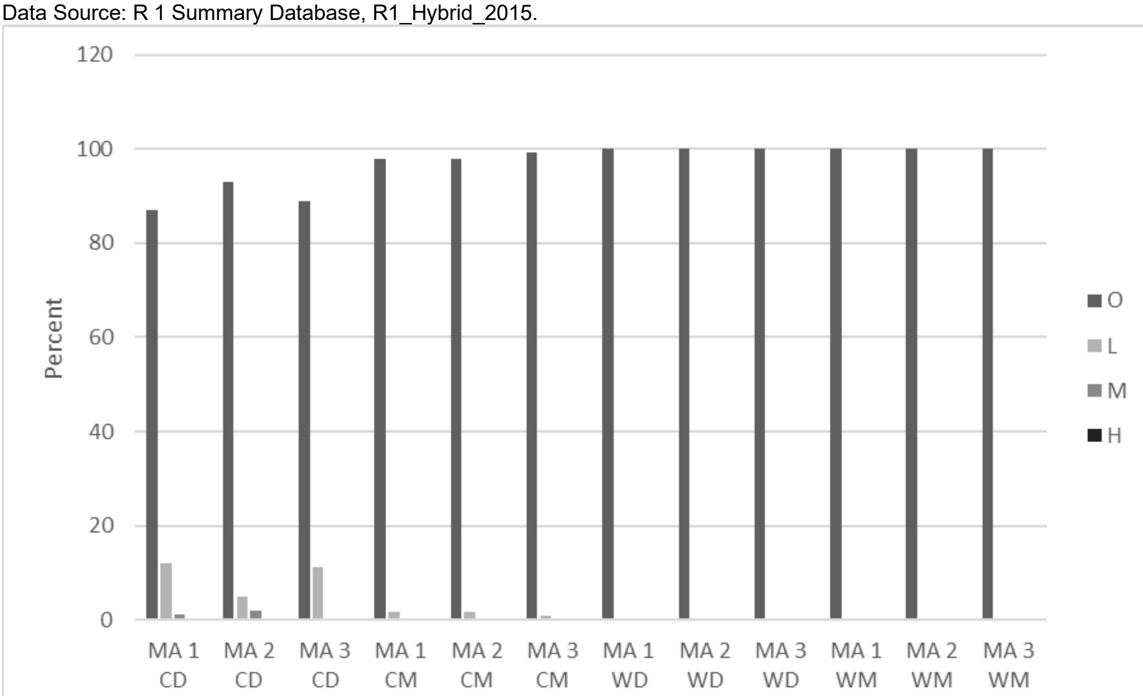

Figure 5. Percent Mountain pine beetle hazard rating for whitebark pine by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015.

Within the cold potential vegetation type groups, the mountain pine beetle averages 9 percent for low hazard rating and less than 1 percent for moderate hazard rating. Within the cool moist potential vegetation type groups, the mountain pine beetle averages 1 percent for low hazard rating. The highest percentage of area effected by the mountain pine beetle occurs in Management Area 1 in the cold potential vegetation type group. Hazard ratings are primarily associated with host species presence. It is expected that if whitebark pine populations continue to decline, as estimated by the Forest Inventory and Analysis (FIA) data then the hazard rating for whitebark pine will decline as well.

The Douglas fir beetle is a chronic mortality agent in Douglas fir forests, occurring in both the warm dry and warm moist broad potential vegetation types and killing or injuring individual and small groups of trees. Outbreaks occur periodically, typically after disturbances such as fire, drought, and windthrow, or where large areas of weakened trees exist. Large diameter trees are the most vulnerable. Typically, only the largest individuals or groups of large trees are killed, creating large snags, downed woody debris, and canopy gaps where new trees become established to create a structurally diverse stand. Douglas fir beetle has been endemic across the Nez Perce-Clearwater over the last decade, although a spike in infestation occurred following the large wildfires of 2015 and 2017 as the insect capitalized on fire-weakened trees. The natural range of variation analysis showed that the acres infested from 1999 to 2015 were at the lower end of the natural range.

The hazard or likelihood of a Douglas fir beetle infestation developing is based on the average diameter of Douglas fir trees, stand basal area, and percent composition of Douglas fir (Randall et al. 2019). Figure 6 displays estimated Douglas fir beetle hazard. Hazard is most likely to be present on warm dry and warm moist broad potential vegetation types. Where susceptible Douglas fir are available, the hazard is primarily low and moderate. This may indicate a limited potential for a large-scale outbreak; however, localized outbreaks are possible, especially where disturbances cause elevated risk and may impact high value stands such as old growth.

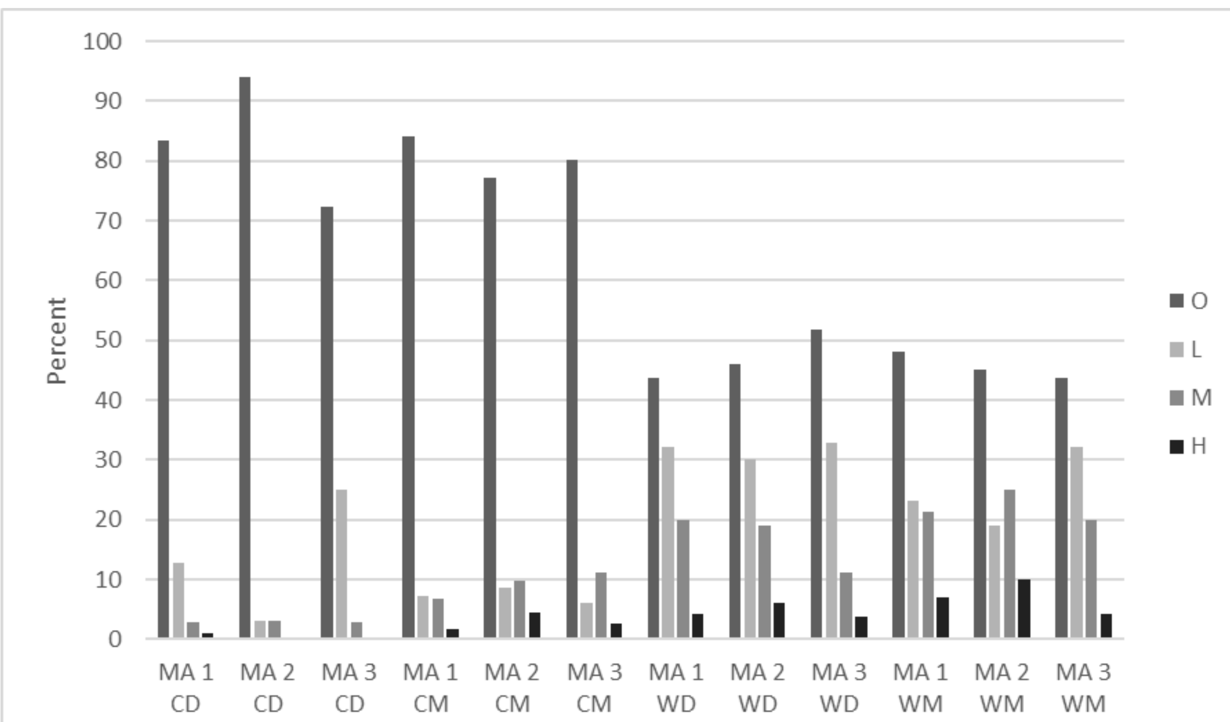

Figure 6. Percent Douglas fir beetle hazard rating for Douglas fir by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015

The warm dry and warm moist potential vegetation type groups have the highest levels of Douglas fir hazard with averages over 10 percent. This is also where Douglas fir is most common. There is moderate to low hazard associated with all potential vegetation type groups across all management areas (Figure 6).

The spruce beetle is a minor mortality agent in spruce and fir forests, killing or injuring individual and small groups of trees at endemic levels. Outbreaks occur periodically, typically after disturbances, such as fire, drought, and windthrow, or where large areas of weakened trees exist. Such outbreaks often result in complete mortality of all large diameter trees. Under endemic conditions, only the largest individuals or groups of large trees are killed, creating large snags, downed woody debris, and canopy gaps where new trees become established to create a structurally diverse stand. Spruce beetle outbreaks at all scales result in a shift in overstory species composition toward subalpine fir.

Figure 7 displays the estimated spruce beetle hazard. This hazard is most likely to be present on cold and cool moist broad potential vegetation types. Where susceptible Engelmann spruce are available, the hazard is primarily low and moderate. This may indicate a limited potential for a large-scale outbreak; however, localized outbreaks are possible, especially where disturbances cause elevated risk and may impact high value stands such as old growth.

The cool moist and cold potential vegetation type groups have the highest levels of spruce beetle hazard with averages of 10 percent. There is moderate and low hazard associated with all potential vegetation type groups across all management areas.

Fir engraver (*Scolytus ventralis*) is another beetle occurring generally at endemic levels across the Nez Perce-Clearwater. Grand fir is the primary host species for this beetle, although subalpine fir may be affected during outbreaks. Outbreaks of fir engraver generally result from drought conditions and are sustained with continuing drought. Fir engraver typically responds to stressed trees within moderate to high density stands (Randall 2012). Contributing factors to tree stress include root disease (Hertert et al. 1975) and defoliation by insects (Berryman 1973, Wright et al. 1984).

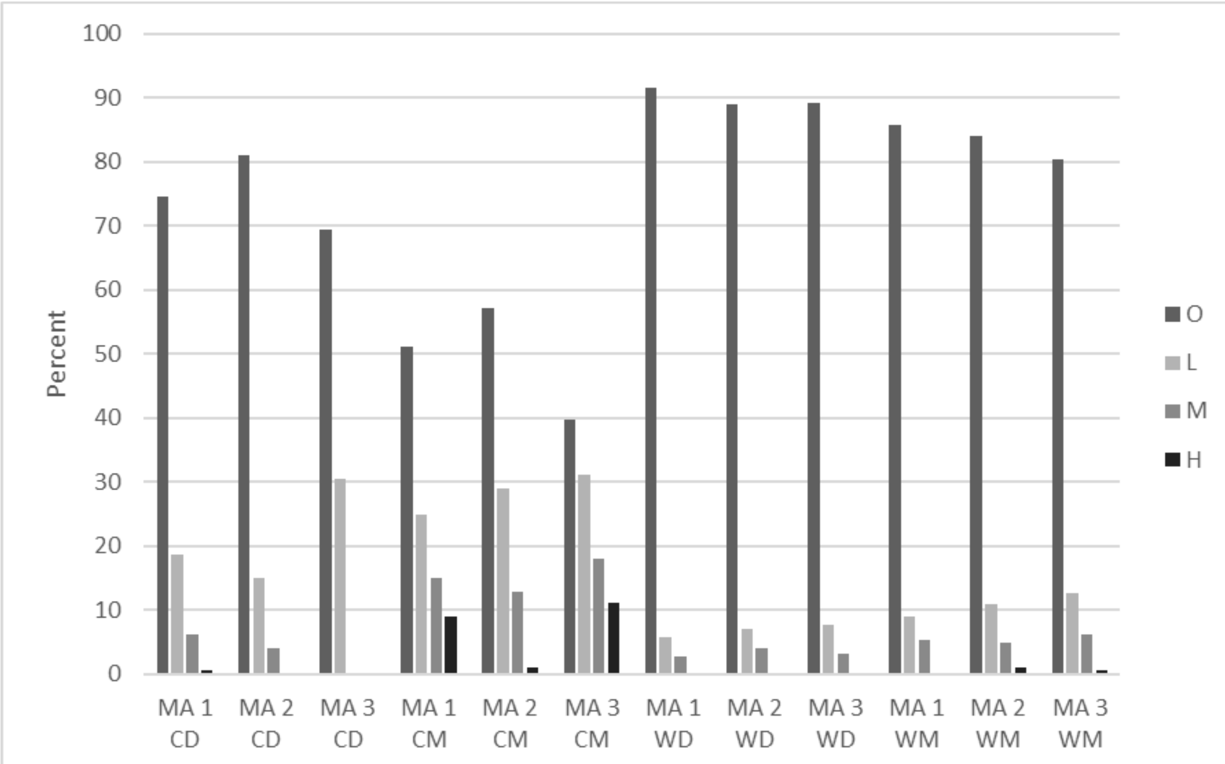

Figure 7. Percent Spruce beetle hazard rating for Engelmann spruce by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015

Dry true fir sites under natural fire regimes that were occupied by pines experience the highest levels of mortality during periods of drought. Fir engraver caused spectacular levels of mortality in true fir forests growing on very dry sites near the forest-grassland interface in southcentral Oregon during a protracted drought period in the late 1980s and early 1990s, sometimes resulting in death of entire stands (Malesky et al. 2020).

Aerial detection surveys (U.S. Department of Agriculture 2019) indicate only endemic levels of fir engraver in Management Areas 1 and 2 across all grand fir habitat types. Grand fir stands within the warm dry potential vegetation type in Management Area 3 are at a moderate hazard level.

Defoliation Insects: The balsam woolly adelgid (BWA) (*Adelges piceae*) is a non-native pest of true fir species that was detected in 1983 within the Palouse River Ranger District of north central Idaho (Livingston et al. 2000). This insect now spans the known range of subalpine fir in Idaho (Davis et al. 2020). Susceptibility of true fir species to BWA varies widely within and among species. Of the native western North American fir species, subalpine fir is the most susceptible. Within five years of infestation, up to 90 percent of stands dominated by subalpine fir died in western Oregon and Washington (Mitchell and Buffam 2001). Five years after BWA was first detected in Idaho, nearly 60 percent of the subalpine fir died, and within 18 years of infestation about 95 percent died across nine monitored sites (Lowrey and Davis 2018). Host susceptibility is probably influenced by genetic variation within species and environmental effects on the host-agent interaction (Newton and Hain 2005). Generally, larger and faster growing trees on preferred growing sites may be infested before suppressed subalpine fir (Mitchell and Wright 1967). There is a visual signature associated with BWA damage and mortality recorded during aerial detection surveys for insects and diseases. Approximately 290,000 acres have experienced some level of damage or tree mortality from this insect between 2000 and 2015. Damage from this pest is often not detectable from air until 30–50 percent of the stand is damaged (Lowrey and Davis 2018).

Management options are limited for this pest. Biological control attempted between 1957 and 1964 (Mitchell and Wright 1967) have not proven to control populations. Research by Havill et al. (Havill et al. 2020) provides a detailed adelgid phylogeny and invasion, including information that the species complex may be transitioning from sexual to asexual reproduction. Insecticides are effective at controlling BWA; however, they are generally limited to urban forests or developed areas and not a realistic option at landscape scales. Silvicultural options have not proven effective management for the balsam woolly adelgid, possibly because this insect can reproduce on true fir of all age classes and disperses passively by wind, birds, and mammals.

The western hemlock looper (*Lambdina fiscellaria lugubrosa*) has been detected on the Nez Perce-Clearwater. Western hemlock looper has become an important and cyclic disturbance agent of Nez Perce-Clearwater forests (Malesky et al. 2020). Tree mortality can occur rapidly, within two years of the start of infestation. The most severe infestations have occurred in coastal and interior wet belt regions, largely in mature hemlock and hemlock-cedar stands (Alfaro et al. 1999). During outbreaks, the western hemlock looper has been reported feeding on several other host tree species and some broad-leaved forest trees and shrubs (Alfaro et al. 1999, McCloskey 2007). Hemlock looper outbreaks may span one to five years and usually begin to collapse around year three due to natural predators, parasites, diseases, viruses, and sometimes weather. In early August 2019, western hemlock looper defoliation was mapped by aerial surveyors in Montana and Idaho. The 2019 aerial surveys were appropriately timed to capture the complete signature from hemlock looper feeding. Idaho had most of the mapped damage, and Montana had approximately 5 percent of the mapped acres of defoliation. The majority of 2019 aerially recorded defoliation occurred in Clearwater and Shoshone counties in northern Idaho and Lincoln County in Montana. The North Fork Ranger District on the Nez Perce-Clearwater experienced the highest number of National Forest System acres impacted from hemlock looper in 2019, equaling 140,076 of 297,000 total acres on the Nez Perce-Clearwater. Surveyors also mapped over 95 percent of the Idaho Panhandle National Forest's hemlock looper damage on the St. Joe Ranger District, totaling 79,000 acres.

Warmer and drier growing season conditions correlate with western hemlock looper population growth. McCloskey et al. (2007) reported periods of soil moisture deficits during the month of June were associated with the onset of western hemlock looper outbreaks, as were warmer and drier conditions during the growing season two years prior to the first year of visible defoliation. In northern Idaho, moderate and severe drought was recorded for multiple growing months in 2017, 2018, and 2019.

The larvae stage of this insect feeds on the live needles and shoots of hemlock species true firs, such as grand fir and subalpine fir, as well as Douglas fir. High levels of mortality were also observed in mature western redcedar. Field reconnaissance of the area indicated high levels of mortality among host species of all size classes. Causes for this outbreak are not yet known and monitoring continues to document the effects and scale of this disturbance. As with most host specific forest pests, the hemlock looper may have an impact on both species' composition and size class distribution of infected stands.

The Western spruce budworm (*Choristoneura occidentalis*) is a major defoliator that can cause mortality in spruce and fir forests under outbreak conditions. Recent decades have seen only endemic levels of this defoliating insect. At endemic levels, individual and small groups of host tree species are affected. Western spruce budworm feed on a wide range of hosts that most commonly include Douglas fir, true firs, spruce, and Western larch and occasionally hemlock and pine species. Outbreaks occur on a 20-to 30-year cycle possibly in association with amount of spring precipitation and may last a few years to over a decade. Such outbreaks often result in top-kill, reduced growth, loss of cone production, and mortality. Severely defoliated trees are more susceptible to attack by bark beetles.

Figure 8 displays estimated Western spruce budworm hazard. This hazard is most likely to be present on cold and cool moist broad potential vegetation types. However, spruce are often associated with riparian areas which occur within all broad potential vegetation types. Where susceptible Engelmann spruce are present, the hazard is primarily low and moderate. This may indicate lower host species density or smaller size classes.

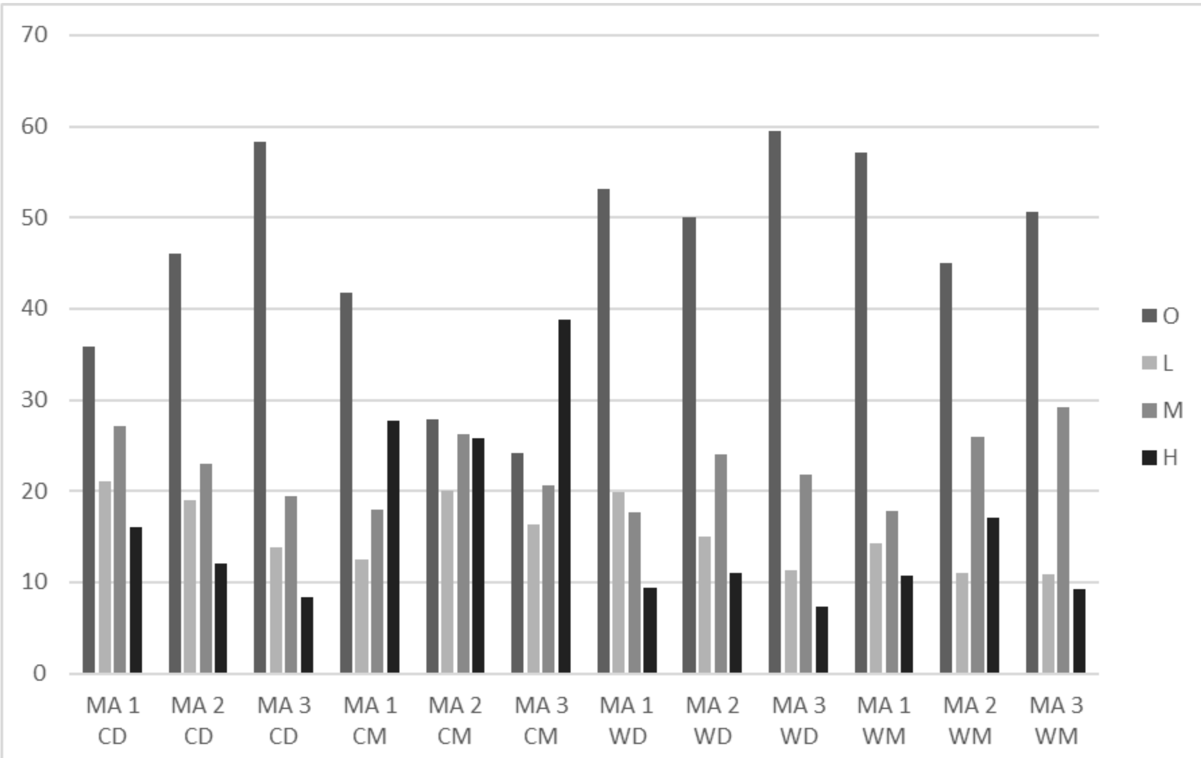

Figure 8. Percent Spruce budworm hazard rating by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating) .

Data Source: R 1 Summary Database, R1_Hybrid_2015.

The cool moist and cold potential vegetation type groups have the highest levels of Western spruce budworm hazard, with averages of 20 percent of the area having a high-risk rating (Figure 8). The highest hazard is found in Management Area 3 within the cool moist broad potential vegetation type. This is generally the result of stands being managed at higher densities. There is a moderate and low hazard associated with all potential vegetation type groups across all management areas.

Root Disease: Root diseases are the most damaging group of tree diseases (U.S. Department of Agriculture n.d.) and are caused by fungi that spread from the roots of diseased trees, dead roots, and rhizomorphs through the soil to uninfected trees and stumps. The most common root pathogens known to occur on the Nez Perce-Clearwater include armillaria (*Armillaria ostoyae*), laminated root rot (*Phellinus weirii*), annosus root disease (*Heterobasidion annosum*), and schweinitzii root and butt rot (*Phaeolus schweinitzii*). These are found throughout the plan area and are associated mostly with stands dominated by true firs, western hemlock, and Douglas fir, although Armillaria and schweinitzii were also commonly found on Douglas fir, grand fir, Ponderosa pine, and Engelmann spruce. Tomentosus root disease was also noted on Engelmann spruce. Evidence for these pathogens includes decayed roots on recent blowdown trees, mycelial fans, basal resinosus, and symptoms of thinning, fading crowns. Root diseases historically contributed to the dominance of white pine and Western larch by reducing other species early in stand development (Smith and Fischer 1997). With the loss of white pine and larch due to the fires of 1910 and 1926, selective timber harvest, and white pine blister rust, the mixed mesic forest is now dominated by the grand fir-cedar-hemlock type with its inherent high susceptibility to root diseases. The heavy incidence of root diseases in this type makes intermediate harvests an untenable option in most situations.

Root disease study plots throughout northern Idaho show that the incidence of root disease has increased over the past 40 years, as has the resulting mortality in susceptible tree species. This increase has been in both the extent of root diseases and the intensity of the diseases. In many cases, this is a result of the loss of Western white pine, which has increased the presence of susceptible species such as Douglas fir and grand fir.

Root disease is the leading cause of tree mortality on the Nez Perce National Forest (22 percent of all mortality) and the Clearwater National Forest (49 percent of all mortality). Root diseases affect more acres on these National Forests than wildland fire, bark beetles, and timber harvest combined. Because root diseases can reduce tree growth and stocking densities for many decades, their effects on forest carbon stocks and flux are more persistent than the effects of other disturbance agents. Root disease can cause mortality as well as increase susceptibility of trees to bark beetle-caused mortality. According to Lockman (2016), “root diseases exceed all other forest insects and diseases in annual volume losses in forests of Northern Idaho and western Montana.” Root disease hazard ratings are relative likelihoods that root diseases exist on a site and are causing significant impact to susceptible species, as shown in Figure 11.

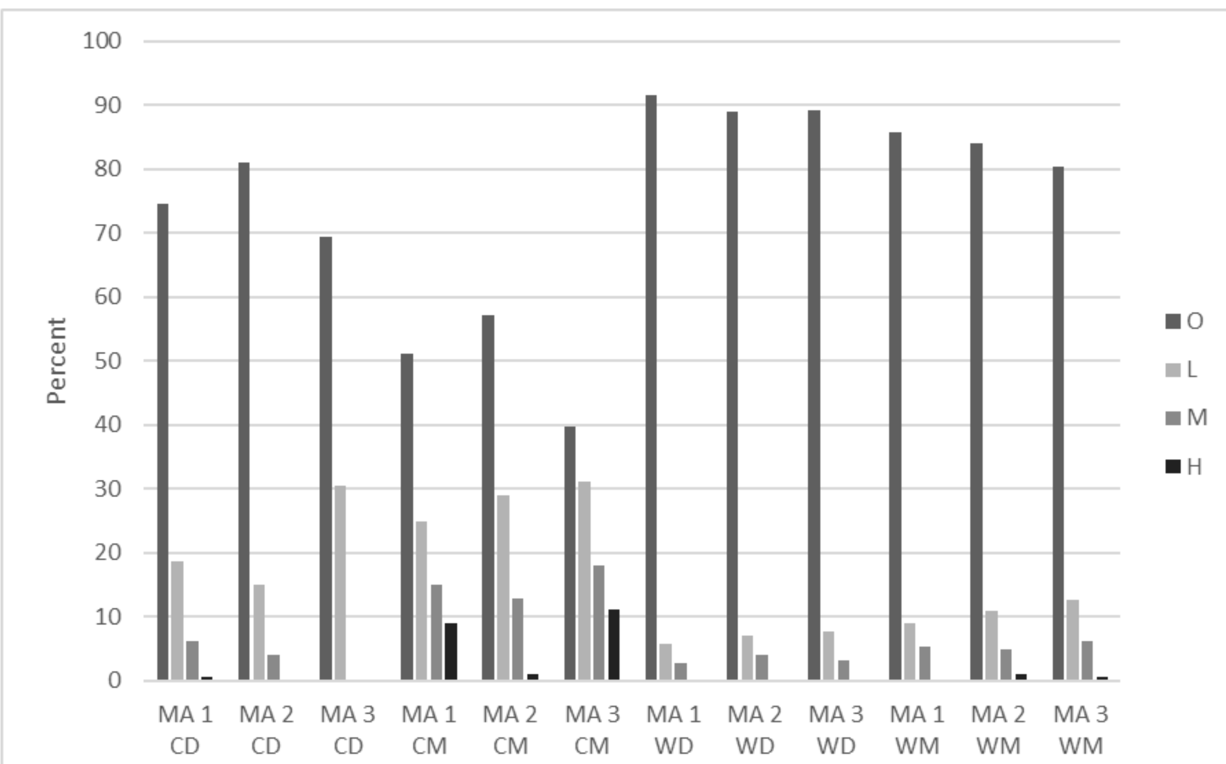

Figure 9. Percent Spruce beetle hazard rating for Engelmann spruce by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015

Dry true fir sites under natural fire regimes that were occupied by pines experience the highest levels of mortality during periods of drought. Fir engraver caused spectacular levels of mortality in true fir forests growing on very dry sites near the forest-grassland interface in southcentral Oregon during a protracted drought period in the late 1980s and early 1990s, sometimes resulting in death of entire stands (Malesky et al. 2020).

Aerial detection surveys (U.S. Department of Agriculture 2019) indicate only endemic levels of fir engraver in Management Areas 1 and 2 across all grand fir habitat types. Grand fir stands within the warm dry potential vegetation type in Management Area 3 are at a moderate hazard level.

Defoliation Insects: The balsam woolly adelgid (BWA) (*Adelges piceae*) is a non-native pest of true fir species that was detected in 1983 within the Palouse River Ranger District of north central Idaho (Livingston et al. 2000). This insect now spans the known range of subalpine fir in Idaho (Davis et al. 2020). Susceptibility of true fir species to BWA varies widely within and among species. Of the native western North American fir species, subalpine fir is the most susceptible. Within five years of infestation, up to 90 percent of stands dominated by subalpine fir died in western Oregon and Washington (Mitchell and Buffam 2001). Five years after BWA was first detected in Idaho, nearly 60 percent of the subalpine fir died, and within 18 years of infestation about 95 percent died across nine monitored sites (Lowrey and Davis 2018). Host susceptibility is probably influenced by genetic variation within species and environmental effects on the host-agent interaction (Newton and Hain 2005). Generally, larger and faster growing trees on preferred growing sites may be infested before suppressed subalpine fir (Mitchell and Wright 1967). There is a visual signature associated with BWA damage and mortality recorded during aerial detection surveys for insects and diseases. Approximately 290,000 acres have experienced some level of damage or tree mortality from this insect between 2000 and 2015. Damage from this pest is often not detectable from air until 30–50 percent of the stand is damaged (Lowrey and Davis 2018).

Management options are limited for this pest. Biological control attempted between 1957 and 1964 (Mitchell and Wright 1967) have not proven to control populations. Research by Havill et al. (Havill et al. 2020) provides a detailed adelgid phylogeny and invasion, including information that the species complex may be transitioning from sexual to asexual reproduction. Insecticides are effective at controlling BWA; however, they are generally limited to urban forests or developed areas and not a realistic option at landscape scales. Silvicultural options have not proven effective management for the balsam woolly adelgid, possibly because this insect can reproduce on true fir of all age classes and disperses passively by wind, birds, and mammals.

The western hemlock looper (*Lambdina fiscellaria lugubrosa*) has been detected on the Nez Perce-Clearwater. Western hemlock looper has become an important and cyclic disturbance agent of Nez Perce-Clearwater forests (Malesky et al. 2020). Tree mortality can occur rapidly, within two years of the start of infestation. The most severe infestations have occurred in coastal and interior wet belt regions, largely in mature hemlock and hemlock-cedar stands (Alfaro et al. 1999). During outbreaks, the western hemlock looper has been reported feeding on several other host tree species and some broad-leaved forest trees and shrubs (Alfaro et al. 1999, McCloskey 2007). Hemlock looper outbreaks may span one to five years and usually begin to collapse around year three due to natural predators, parasites, diseases, viruses, and sometimes weather. In early August 2019, western hemlock looper defoliation was mapped by aerial surveyors in Montana and Idaho. The 2019 aerial surveys were appropriately timed to capture the complete signature from hemlock looper feeding. Idaho had most of the mapped damage, and Montana had approximately 5 percent of the mapped acres of defoliation. The majority of 2019 aerially recorded defoliation occurred in Clearwater and Shoshone counties in northern Idaho and Lincoln County in Montana. The North Fork Ranger District on the Nez Perce-Clearwater experienced the highest number of National Forest System acres impacted from hemlock looper in 2019, equaling 140,076 of 297,000 total acres on the Nez Perce-Clearwater. Surveyors also mapped over 95 percent of the Idaho Panhandle National Forest's hemlock looper damage on the St. Joe Ranger District, totaling 79,000 acres.

Warmer and drier growing season conditions correlate with western hemlock looper population growth. McCloskey et al. (2007) reported periods of soil moisture deficits during the month of June were associated with the onset of western hemlock looper outbreaks, as were warmer and drier conditions during the growing season two years prior to the first year of visible defoliation. In northern Idaho, moderate and severe drought was recorded for multiple growing months in 2017, 2018, and 2019.

The larvae stage of this insect feeds on the live needles and shoots of hemlock species true firs, such as grand fir and subalpine fir, as well as Douglas fir. High levels of mortality were also observed in mature western redcedar. Field reconnaissance of the area indicated high levels of mortality among host species of all size classes. Causes for this outbreak are not yet known and monitoring continues to document the effects and scale of this disturbance. As with most host specific forest pests, the hemlock looper may have an impact on both species' composition and size class distribution of infected stands.

The Western spruce budworm (*Choristoneura occidentalis*) is a major defoliator that can cause mortality in spruce and fir forests under outbreak conditions. Recent decades have seen only endemic levels of this defoliating insect. At endemic levels, individual and small groups of host tree species are affected. Western spruce budworm feed on a wide range of hosts that most commonly include Douglas fir, true firs, spruce, and Western larch and occasionally hemlock and pine species. Outbreaks occur on a 20-to 30-year cycle possibly in association with amount of spring precipitation and may last a few years to over a decade. Such outbreaks often result in top-kill, reduced growth, loss of cone production, and mortality. Severely defoliated trees are more susceptible to attack by bark beetles.

Figure 8 displays estimated Western spruce budworm hazard. This hazard is most likely to be present on cold and cool moist broad potential vegetation types. However, spruce are often associated with riparian areas which occur within all broad potential vegetation types. Where susceptible Engelmann spruce are present, the hazard is primarily low and moderate. This may indicate lower host species density or smaller size classes.

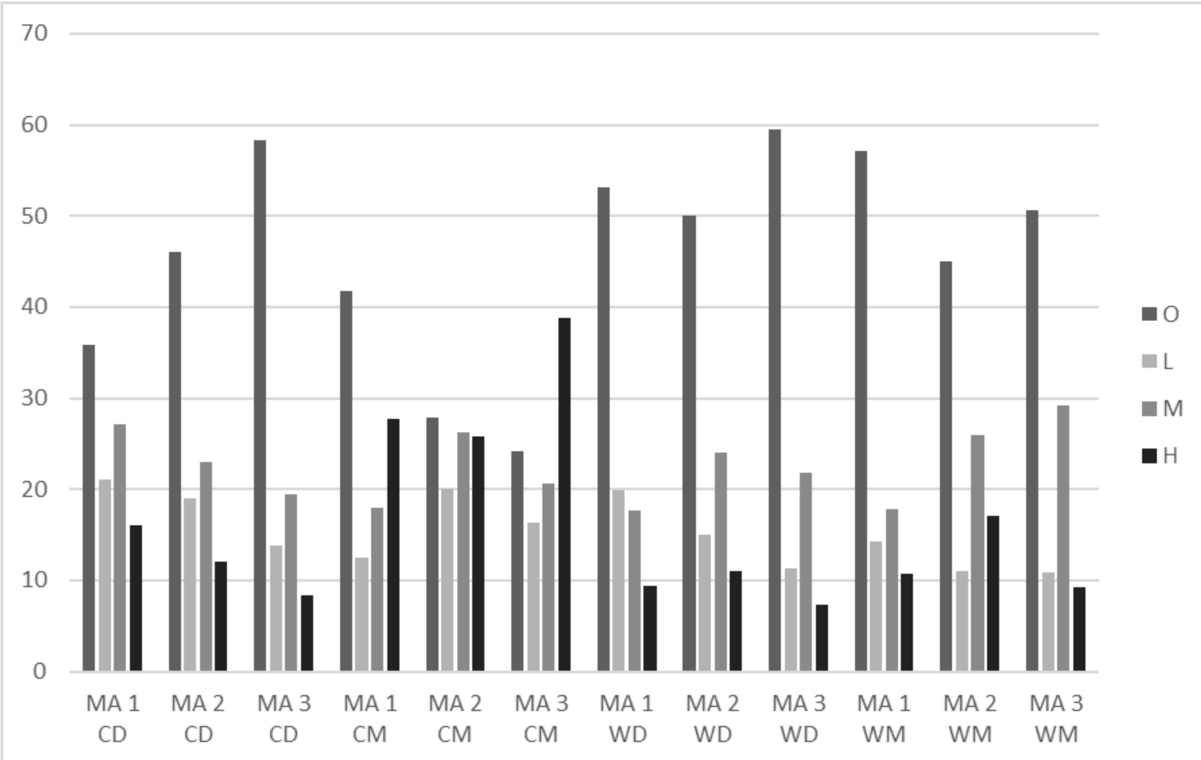

Figure 10. Percent Spruce budworm hazard rating by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015.

The cool moist and cold potential vegetation type groups have the highest levels of Western spruce budworm hazard, with averages of 20 percent of the area having a high-risk rating (Figure 8). The highest hazard is found in Management Area 3 within the cool moist broad potential vegetation type. This is generally the result of stands being managed at higher densities. There is a moderate and low hazard associated with all potential vegetation type groups across all management areas.

Root Disease: Root diseases are the most damaging group of tree diseases (U.S. Department of Agriculture n.d.) and are caused by fungi that spread from the roots of diseased trees, dead roots, and rhizomorphs through the soil to uninfected trees and stumps. The most common root pathogens known to occur on the Nez Perce-Clearwater include armillaria (*Armillaria ostoyae*), laminated root rot (*Phellinus weirii*), annosus root disease (*Heterobasidion annosum*), and schweinitzii root and butt rot (*Phaeolus schweinitzii*). These are found throughout the plan area and are associated mostly with stands dominated by true firs, western hemlock, and Douglas fir, although Armillaria and schweinitzii were also commonly found on Douglas fir, grand fir, Ponderosa pine, and Engelmann spruce. Tomentosus root disease was also noted on Engelmann spruce. Evidence for these pathogens includes decayed roots on recent blowdown trees, mycelial fans, basal resinosus, and symptoms of thinning, fading crowns. Root diseases historically contributed to the dominance of white pine and Western larch by reducing other species early in stand development (Smith and Fischer 1997). With the loss of white pine and larch due to the fires of 1910 and 1926, selective timber harvest, and white pine blister rust, the mixed mesic forest is now dominated by the grand fir-cedar-hemlock type with its inherent high susceptibility to root diseases. The heavy incidence of root diseases in this type makes intermediate harvests an untenable option in most situations.

Root disease study plots throughout northern Idaho show that the incidence of root disease has increased over the past 40 years, as has the resulting mortality in susceptible tree species. This increase has been in both the extent of root diseases and the intensity of the diseases. In many cases, this is a result of the loss of Western white pine, which has increased the presence of susceptible species such as Douglas fir and grand fir.

Root disease is the leading cause of tree mortality on the Nez Perce National Forest (22% of all mortality) and the Clearwater National Forest (49% of all mortality). Root diseases affect more acres on these National Forests than wildland fire, bark beetles, and timber harvest combined. Because root diseases can reduce tree growth and stocking densities for many decades, their effects on forest carbon stocks and flux are more persistent than the effects of other disturbance agents. Root disease can cause mortality as well as increase susceptibility of trees to bark beetle-caused mortality. According to Lockman (2016), "root diseases exceed all other forest insects and diseases in annual volume losses in forests of Northern Idaho and western Montana." Root disease hazard ratings are relative likelihoods that root diseases exist on a site and are causing significant impact to susceptible species, as shown in Figure 11.

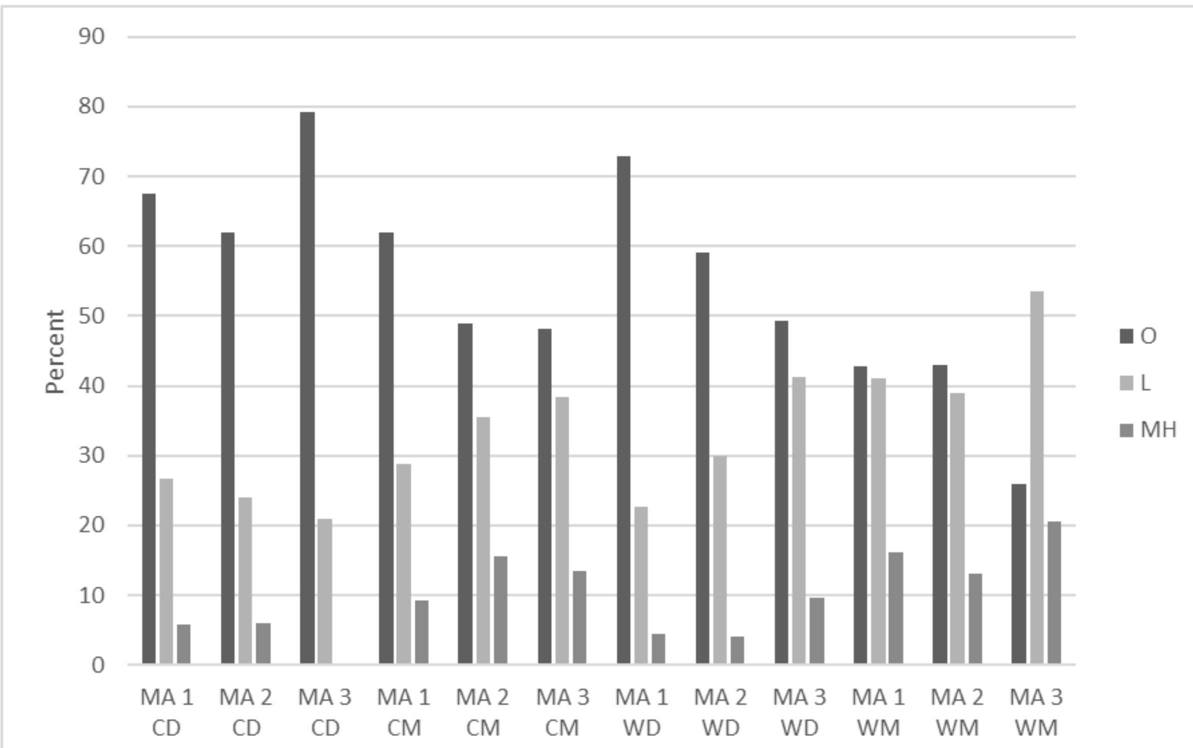

Figure 11. Percent Percentage of area exhibiting low, medium, and high ratings for root disease by management area and potential vegetation type (O=none, L=Low, M=Moderate, H=High hazard rating).

Data Source: R 1 Summary Database, R1_Hybrid_2015.

Incidence of root disease is summarized from Forest Inventory and Analysis (FIA) data. Root disease is generally at low levels across all potential vegetation type groups and management areas with an average of 33 percent low hazard rating. A low hazard rating includes data for FIA plots with no evidence of root disease, plots with evidence of root disease within 50 feet of the surveyed plot, and plots with minor evidence of root disease. Moderate root disease risk hazard is common across all potential vegetation type groups and management areas with an average of 18 percent of each area affected. Areas exhibiting moderate root disease are characterized as having between 20 and 50 percent canopy reduction and 30 to 50 percent of tree mortality is caused by root disease. High root disease hazard averages less than 10 percent forestwide. High root disease areas are characterized as 50 to 75 percent canopy reduction and most tree mortality is directly related to root disease.

White Pine Blister Rust: White pine blister rust is a non-native disease that entered the United States at the turn of the twentieth century. Its primary host species on the Nez Perce-Clearwater are Western white pine, whitebark pine, and five-needle pine (*Pinus parviflora*). It also infects Ribes species (currants and gooseberries) and possibly louseworts (*Pedicularis* spp.) and Indian paintbrush (*Castilleja* spp.), which are alternative hosts required for the disease to complete its life cycle (Geils et al. 2010). As blister rust has moved into fragile, high-elevation ecosystems, successional pathways have been altered, hastening the conversion to climax species, such as subalpine fir. Blister rust infections range in severity but often progress from infecting and girdling branches to killing trees of all sizes over time. Surviving trees are weakened and susceptible to other mortality agents, such as the mountain pine beetle. The interaction of warming climates; mountain pine beetle; fire exclusion, which has allowed shade tolerant species to outcompete whitebark pine; and blister rust has resulted in a bleak outlook for whitebark pine in many areas.

Because it is non-native, all levels of blister rust infection are outside the natural range of variation. There is no known method for eradicating the disease, although actions, such as pruning, can reduce points of spore entry and infections. A small percentage of host trees display one or more resistance traits that enable them to avoid or survive infection, encouraging natural or artificial regeneration from these seed sources and providing hope for perpetuation of the species. In addition to native resistance to white pine blister rust, there has been a successful western white pine resistance breeding program over the last 30 years that has produced improved stock which is currently out-planted to help maintain and expand this species current range. A selective breeding program has been initiated for whitebark pine to help stabilize this species current decline. There is currently no statistical means to estimate blister rust infection or hazard across the Nez Perce-Clearwater. Based on field experience, however, white pine blister rust is generally present wherever five-needle pines are found.

Timber Harvest

Previous harvest activities within the project area set the stage for forest cover types to depart from historical species distributions. Neuenschwander et al. (1999) give an excellent history on the decline of western white pine and the synergism between previous harvest and blister rust that caused the forest to be altered so radically:

"By the late 1950s, Inland Northwest National Forests accelerated timber harvests to meet timber demand resulting from the post-World War II housing boom. At the same time, despite Ribes control efforts, blister rust mortality accelerated in mature white pine. By the 1960s it became obvious that the war against Ribes was lost. In 1968, the Forest Service officially abandoned both its Ribes control efforts and its antibiotic treatments of white pine. This policy discontinued planting of non-blister rust resistant white pine, emphasized regeneration and thinning of species mixes that did not include white pine, and focused major commercial timber harvests on white pine groves threatened by blister rust. Commercial harvests after 1968 were clearcuts planted with Douglas fir. Most of the remainder were partial harvests that removed white pine and left other trees in the forests. Not only were dead and dying white pine harvested, but entire populations of white pine were removed, effectively also removing any blister rust-resistant genes that might have remained. From the 1960s through the mid-1970s the areas formerly holding the best mature white pine groves were being converted to other trees, predominantly Douglas fir, grand fir, and hemlock."

An example of disturbance history resulting from selective timber harvest can be found in the French Larch area of the Clearwater National Forest. The French Larch project area would not have been exempt from white pine management strategies and it is highly likely that the area was affected as described in the Neuenschwander et al. (1999) history.

About 6,524 acres of the French Larch project area have been regeneration harvested since 1964, with much of this harvest very likely focused on removing Western white pine. The earliest recorded regeneration harvest found through data query beginning in 1900 was in 1964. Areas that were regenerated up until the 1980s would likely not have been replanted with any white pine; these areas would probably have been planted with Douglas fir (Nuenschwander et al. 1999) or left to regenerate naturally. In areas where Western white pine salvage occurred as a partial harvest, canopy openings would have been small enough that growing conditions would be more favorable for more shade tolerant species. Likewise, in these areas, since the goal was to remove white pine before it was killed by blister rust, there would have been no seed source retained to allow white pine to regenerate naturally. Thus, due to past harvest removing seed sources creating conditions unfavorable for white pine and focusing on planting species other than white pine, the forest cover types in this area show their current departure from historic conditions.

In addition to natural ecosystem processes, human interventions change vegetation. Two broad categories of vegetation treatment are evaluated: timber harvest and prescribed fire. Timber harvest consists of three general types. Table 17 provides a summary of how treatments generally affect vegetation.

Table 17. Description of vegetation treatment types and effects.

Treatment	Description
Even-aged regeneration harvest	Even-aged regeneration harvest includes clearcuts, seed tree, and shelterwood cuts with or without reserves. These cuts remove most overstory trees and allow new seedlings to establish. The size class changes to seedling or sapling (single or two-storied structure), initially with low canopy cover. Cover type and species presence may change. Downed wood and snags may change often. Natural regeneration or tree planting occurs, which influences species composition and forest density. Later, non-commercial thinning may occur in sapling stands, reducing densities, and affecting species compositions and structure over the long-term.
Uneven-aged regeneration harvest	Single or group selection are types of uneven-aged silvicultural systems, which establish a new seedling or sapling size class and may change species composition. Unlike even-aged regeneration harvest, the conversion of existing stands occurs gradually over many decades, creating a multi-age and multi-size stand. Small openings are created with each entry while the remainder consists of the existing overstory. For example, a stand could have a treatment every 20 years, creating openings on 20% of the stand each time, resulting in the entire stand being treated over 100 years. Reforestation and stand tending may be used to affect species composition and structure. Reduction of downed wood and snags may occur.
Intermediate harvest	Intermediate harvests enhance growth, quality, vigor, and composition of an existing stand and do not cause a shift to a seedling or sapling condition. Treatments in this category include commercial thinning, liberation harvest, sanitation or salvage, and improvement cutting. These treatments leave a forest that is still dominated by trees larger than saplings. The focus is not on regenerating a new forest but in changing the condition of the current one. Not only is forest density reduced, but species compositions and forest size class may change. Tree growth is typically accelerated. Reduction of downed wood and snags may occur.
Prescribed fire and fuel reduction	Prescribed fires are planned ignitions where fire is deliberately applied to the landscape. In the past, prescribed fire and fuel treatments generally occurred after harvest to reduce woody fuels and prepare the site for reforestation. Today, fire and fuel reduction activities are also used to restore ecosystem processes, improve resilience, reduce fire risk, and to improve wildlife habitat, and may be implemented as

Treatment	Description
	stand-alone vegetation treatments. Outcomes of prescribed fire can vary depending on site conditions and objectives. Typically, more open forest structures and shade intolerant species compositions are enhanced. Other vegetation manipulations, such as slashing and piling of fuels, may also occur.

Harvest activities prior to the 1940s were associated with homesteading, mining, and railroad building. These activities were concentrated in easily accessible or productive forests. In some cases, forests were cleared for uses, such as fuelwood, while, in others, only the selected removal of the largest and best trees, or "high-grading," occurred. While no data are readily available to quantify early harvests, they undoubtedly helped shape the forests that exist today. Since the 1900s, harvest records have been kept. Since that time, harvest has impacted roughly 40 percent of the Nez Perce-Clearwater's landbase. Table 18 shows the acres of treatments conducted by decade since 1987.

Table 18. Average number of acres of vegetation treatments by decade, 1987-2021.

Decade	Harvest[1]	Prescribed Fire[2]	Fuel Reduction[3]
1987-1996	25,827 acres	24,706 acres	20,443 acres
1997-2006	10,299 acres	39,154 acres	15,667 acres
2007-2016	1,873 acres	8,028 acres	3,737 acres
2017-2021	2,555 acres	1,928 acres	1,700 acres

[1] Harvest activities include even-aged, uneven-aged, and intermediate harvest treatments.

[2] Includes overlap of burning in harvested stands. Prescribed fire activities include broadcast burning, jackpot burning, site preparation burning, and under burning. Wildfire acres are not included; see the Fire Management section for information on past wildfires, including those used for resource benefit.

[3] Fuel reduction treatments include burning of piled material, chipping of fuels, compacting or crushing of fuels, fuel break, miscellaneous treatment of natural fuels, piling of fuels, rearrangement of fuels, and thinning for hazardous fuels reduction.

Data Source: FACTS database, acres completed by fiscal year up to September of 2018.

Salvage Harvest

The term "salvage" indicates that trees being removed were killed by natural disturbance, most commonly wildfire or insects, with one purpose of the treatment being to capture their economic value. Salvage typically only occurs on lands suitable for timber production. Salvage is not modeled as a vegetation treatment as part of the potential forest management solution because it is unpredictable and would not contribute to estimated timber outputs, as defined in the planning directives. The term salvage is only used when the treatment is intermediate in nature; that is, a fully stocked stand remains in place after the cutting. In the case of stand-replacing disturbance, salvage results in an even-aged regeneration silvicultural system and is termed as such depending on the availability of desirable live trees, including clearcut, seed tree, or shelterwood harvest. Acres of "salvage," both intermediate salvage and regeneration harvest, are included in the acres of harvest listed in Table 18. As described in the Timber section, salvage has occurred on approximately 18 percent of the wildfire acres burned since 1987.

Salvage harvest activities have taken place on the Nez Perce-Clearwater for as long as harvesting of live timber. As white pine blister rust began to cause widespread mortality of mature Western white pine stands, the number of salvage harvest acres increased. Typical harvesting practices would also remove live Western white pine, along with salvaged timber. The result of this practice reduced the number and distribution of mature seed producing Western white pine, which in turn reduces Western white pine regeneration.

Wildland fire continues to be a cause of tree mortality and often generates the need for salvage harvesting. Wildland fire affects all dominance types across all potential vegetation type groups.

Prescribed Burning

The Nez Perce-Clearwater has used prescribed fire on the landscape for the past several decades. Objectives of treatment are varied and include reduction of forest fuels, site preparation following harvest, and improvement of wildlife habitat. Prescribed fire can influence vegetation conditions in a similar manner to wildland fires. The use of prescribed fire is intended to have an impact on successional pathways and stand development. As seral dominance types maintained on the landscape by natural wildland fire events emerge, the use of prescribed fire is used to mimic this natural disturbance pattern. Prescribed burning also has an impact on snag recruitment and retention, as well as coarse woody material accumulations. During the last 30 years, the Nez Perce-Clearwater has used prescribed burning on approximately 70,641 acres.

Terrestrial Vegetation

The coarse filter for vegetation composition is portrayed by two indicators: forested and non-forested cover types and tree species distribution. Desired conditions are enumerated in the Land Management Plan. These desired conditions would not necessarily apply to the No Action Alternative but are included in the analysis for all alternatives to provide for a consistent comparison.

Cover types are groupings of dominance types, which are used to simplify analysis at the broad scale. Dominance types describe the most common plant species present. Dominance type and cover type describe assemblages of species and are named after the most dominant species. Information on how dominance types are determined is found in Barber et al. (2011), and a description of cover types is found in Milburn et al. (2015) and Appendix B. There are seven coniferous cover types and one hardwood cover type on the Nez Perce-Clearwater and three vegetated non-forested cover types, as shown in Table 19. Currently all non-forested cover types are not classified. For the quantitative analysis, all vegetated non-forested cover types are lumped together. The non-forest cover type is tracked separately.

Table 19. Cover types and associated dominance type descriptions.

Cover type	Description of Dominance type
Ponderosa pine	This cover type includes sites dominated by Ponderosa pine or Douglas fir. A minor component of grand fir may be present. Ponderosa pine is found within the elevational band between non-forested types and Douglas fir forests. This cover type usually grows on the warm dry broad potential vegetation type.
Dry Douglas fir	This cover type is found on dry sites dominated by Douglas fir with potential components of Ponderosa pine and grand fir. This cover type occurs primarily on the warm dry broad potential vegetation type.
Mixed mesic conifer	This cover type encompasses moist sites dominated by Douglas fir, cedar, white pine, grand fir, and western hemlock. Stands may be mixed with lodgepole pine, Western larch, or subalpine fir and spruce. This type is found on sites moister and more productive than the dry Douglas fir type. This cover type is found on both warm dry and cool moist broad potential vegetation groups.
Western larch mixed conifer	These sites are dominated by Western larch with components of Douglas fir, grand fir, lodgepole pine, or spruce. This type is commonly found on the cool moist broad potential vegetation type.

Cover type	Description of Dominance type
Lodgepole pine	This type is dominated by lodgepole pine with minor components of other species. This cover type can occur on any forested broad potential vegetation group.
Aspen and hardwood	This cover type includes areas dominated by aspen or cottonwood, often with shrubs such as willow and alder. This type often occurs in association with riparian and moist upland areas and can be found in any forested broad potential vegetation group.
Spruce or fir	This cover type describes where subalpine fir or Engelmann spruce dominate with minor components of lodgepole pine and other species. These are often climax forests. This cover type most often occurs on the cool moist or cold broad potential vegetation group.
Whitebark pine	The whitebark pine cover type occurs at the high elevations, most commonly on the cold broad potential vegetation group but sometimes in cool moist. Minor components of subalpine fir, spruce, or lodgepole pine may be present.
Grass	Grass can dominate the xeric and mesic grassland broad potential vegetation groups and some dry forest types. Native plant communities include forb mixes: Idaho fescue, bluebunch wheatgrass, prairie junegrass, tufted hairgrass, mountain brome, needlegrass, and mixed grass. Common non-native species include timothy, orchard grass, Kentucky bluegrass, and annual brome.
Dry shrub	The dry shrub cover type occurs on the xeric shrub and woodland broad potential vegetation group, as well as some dry forest sites. Dominant shrubs include curl-leaf mountain mahogany and sumac.
Riparian Grass or shrub	This cover type occurs typically in the riparian or wetland broad potential vegetation group but also potentially in cool and wet forest habitat types. Common species include willow, alder, tufted hair grass, red top, mountain brome, smooth brome, dry sedge, and wet sedge or spikerush or juncus.
Non-Vegetated	Sites dominated by non-vegetative components, such as rock, water, and urban.

To estimate grassland areas and acreages, Region 1 VMap lifeform data was clipped to mollisol soils from the No SSURGO Data. This query identified 31,837 acres of grassland. To estimate meadow areas, Region 1 VMap data were clipped to the GIS management areas feature class (LIFEFORM = 3100 [HERB] and TREESIZE = 3100 [HERB] or LIFEFORM = 7000 [SPVEG] and TREESIZE = 7000 [SPVEG]) and SLOPE <= 5). This query identified 14,878 acres of meadow. A similar exercise identified an additional 3,000 acres of potential meadow with the encroachment of conifers.

Tree species presence indicates the proportion of an area where there is at least one live tree per acre of a given species. This measure gives an indication of how widely distributed the species is, although it is not necessarily dominant or even common in all the places it occurs. Most stands are composed of more than one tree species. As noted above, cover types are named for the dominant species representing the group, such as the Ponderosa pine cover type. However, Ponderosa pine as an individual species may also be found in other cover types. Therefore, the estimates for a cover type are not the same as the distribution of the individual tree species for which it is named. There are 14 native conifer tree species found on the Nez Perce-Clearwater: Ponderosa pine, Douglas fir, grand fir, lodgepole pine, Western larch, Western white pine, western redcedar, western hemlock, mountain hemlock, Pacific yew, Engelmann spruce, subalpine fir, alpine larch, and whitebark pine. Several hardwood tree species are present and may be intermixed with conifer species or may occur as single species patches on suitable landscapes. Hardwood species include quaking aspen, paper birch, water birch, cottonwood spp., mountain ash, mountain mahogany, and Rocky Mountain maple.

The following sections provide a summary of the ecological role of each tree species and non-forested vegetation type on the Nez Perce-Clearwater. Xeric ecotones and savannas, areas which straddle the concept of forested and non-forested potential vegetation types, are also discussed.

Aspen and Cottonwood

Persistent hardwood-dominated plant communities are rare on the Nez Perce-Clearwater but are important components of diversity, providing habitat for a variety of birds and other wildlife species. Aspen is more common than cottonwood on the Nez Perce-Clearwater. Aspen may occur as a persistent community in riparian areas or as a transitional community in upland areas. These communities often dominate in the early stages of forest succession immediately after disturbance. Aspen historically relied on fire or disease to remove the overstory, killing encroaching conifers and stimulating suckers from the existing clone root system (Shepperd 1990b). Without periodic self-regeneration, aspen stands become decadent and deteriorate as root systems decline; mature clones can also decline due to repeated animal herbivory (Shepperd et al. 2001). Aspen may coexist with conifers for decades after a disturbance, but aspen gradually declines and is replaced by conifer forest as conifers become more numerous and denser.

On the Nez Perce-Clearwater, cottonwood is confined to riparian areas with fluctuating water tables and is more common on the private lands outside of the forest boundary. While present in limited areas, it is poorly represented by available data. It is desirable to maintain and promote this species where it exists, but no quantitative desired condition was developed because it is absent from available data sources in all management areas.

Forestwide, the natural range of variation analysis indicates that the aspen or hardwood cover type is generally within its natural range for abundance, although it is at the low end or slightly below its natural range in all management areas. The modeling also showed that aspen species distribution is below its natural abundance at the forestwide scale and in the warm dry and cool moist broad potential vegetation groups. At the management area level, aspen is below the desired condition in all management areas. The desired condition ranges reflect a desired trend of maintaining and increasing aspen. The highest levels of aspen correlated with past warm, dry climate periods.

Ponderosa pine and Dry Douglas fir Forests

Ponderosa pine is often the only tree species that can colonize the hot, dry surface conditions of a disturbed site. This distinction is especially true on the biophysical settings adjoining the Salmon River, South Fork Clearwater River, and Selway River and, to a lesser extent, along the Lochsa River. Areas on the Palouse Ranger District adjacent to the prairie also support this dominance type. Over time, as Ponderosa pine matures, it provides a shaded environment where less heat tolerant Douglas fir and other species can establish. With frequent understory fires as part of the dominant low-severity fire regime, the thick-barked Ponderosa pine survives while the thinner-barked Douglas fir and Ponderosa pine seedlings do not. If frequent fires are sustained, the Ponderosa pine forest can develop into large patches of open grown old forest structure intermixed with smaller openings that can persist for centuries provided moisture and temperature regimes do not dramatically change. During a cool, wet climatic timespan or through fire suppression, young Douglas fir and Ponderosa pine may become established; in a few decades, this change can result in a dense forest structure. The increased biomass and structural heterogeneity of these dense stands allow fires to develop into large, active crown fires that bring the site back to the initial stand establishment phase or, if fire reburns these areas soon, may limit forest establishment due to loss of seed source, limited soil moisture, and high surface soil temperature.

Western larch Mixed Conifer Forests

These forests developed under fire regimes that included infrequent stand-replacing fires (more than 200 years) and more frequent (20–100 years) mixed severity fires. On mesic sites, these forests produced a diverse pattern of Western larch and Douglas fir with grand fir, Western white pine, and other species sometimes found in the mix. On cooler sites, these forests included Western larch mixed with lodgepole pine, Engelmann spruce, and subalpine fir. These sites were dominated by lethal fire regimes that produced very large patches with older legacy larch often represented. Many old Western larch trees can be found with evidence of fire scars dating back centuries. Western larch is not very susceptible to insects and diseases common to other associated tree species. As such, it brings fire and disease resistance to the forest, making the forest resilient to those disturbances. These forests are perhaps the most scenic with their October change in color.

All larch forests typically had relict, old trees with younger larch and other species forming a second cohort. This two-aged structure was maintained by periodic low-severity fire that visited many stands one, two, or even three times between stand-replacing fires. The presence of low-severity fire allowed complex, old forest structures to persist for many centuries as larch can be a very long-lived seral species.

Grand Fir, Douglas fir, Cedar, and Hemlock Forests

Mixed species shade-tolerant forests are found where fire return intervals are long, allowing these late seral fire-sensitive species to dominate. This is especially true on grand fir mosaic sites, which are cooler and moister than similar non-mosaic sites. Mosaic sites often have very little evidence of fire. Old grand fir or subalpine fir usually dominate there with some western redcedar, Engelmann spruce, and the occasional Western white pine.

Outside of the mosaic stands, these forests are the most diverse on the forest. Any native forest species can be found mixed with the dominant species here. They see a very wide range of fire occurrence. Stand-replacing fires occur every 25 to 200 plus years with shorter return intervals, seral shrub fields, and dominate seral conifer species. Between stand-replacing fire events, non-lethal or mixed severity fires result in a diverse forest with multiple age and size classes.

Root disease is widespread in these stands and is particularly damaging to Douglas fir and grand fir. Annual losses of 5 percent of the basal area in a stand are typical. Openings regenerate with the same species and are subsequently infected with root disease, then the cycle repeats. Western redcedar has long been considered to be tolerant of root disease, but recent observations indicate that it too is seeing the effects with increasing crown thinning and mortality.

Western white pine Forests

Western white pine was a prominent species on sites with western redcedar as the potential vegetation type. Most of this potential vegetation type is found north of the Lochsa River. Prior to the early 1900s and the introduction of white pine blister rust, white pine dominated these sites. Before the advent of blister rust, white pine stands originated after severe, stand-replacing fires that occurred during relatively dry climatic periods (Arno 1980). White pine was maintained by more frequent low- to mixed-severity fires. Blister rust is a non-native disease and white pine rapidly succumbed to infections since it had not coevolved with this pathogen over its history.

As white pine forests have been lost to white pine blister rust, the trees replacing them were often western hemlock, grand fir, and Douglas fir. These species are extremely susceptible to root disease. Douglas fir, for instance, often dies out by the time it is 80 to 100 years old. The stand regenerates to more grand fir, Douglas fir, or western hemlock in the North Fork Clearwater River drainage and on the Palouse Ranger

District. These young trees again succumb to root disease, and this cycle reduces regeneration of forests occupying these same sites today.

Significant progress has been made toward developing rust resistant white pine for out planting in many areas of northern Idaho. Trees grown from the current seed sources are about 60 percent resistant to blister rust. In addition, natural reproduction from surviving white pine trees has shown an approximately 18 percent survival rate and offers another source of blister rust resistance (Hoff et al. 1976).

Lodgepole pine Forests

Lodgepole pine stands are extensive on the subalpine biophysical settings, and lodgepole forests are typically even-aged, single-story forests. Once they reach 60 to 80 years old with a stand size over 8 inches diameter at breast height, they often experience severe mortality caused by mountain pine beetle activity, which creates snags and downed wood. These snags and downed wood produce fuel conditions that lead to potentially severe fire effects, depending on time since the infestation (Jenkins et al. 2008). On lodgepole pine-dominated sites, stand-replacing fire was common, and severity was affected by periodic outbreaks of mountain pine beetle that led to large fuel loads and pulse events for snags. Under moderate fuel loading and fuel moisture conditions, fire effects may result in a mosaic of tree mortality and fuel loading. Such stands may experience reburns which further promotes heterogeneity at landscape scales. If the stands avoid severe fires or reburns, they eventually go through succession to a forest of mixed subalpine fir and Engelmann spruce.

Whitebark Pine, Subalpine Fir, and Engelmann Spruce Forests

Whitebark pine is associated with high elevation and its distribution has been primarily influenced by the cold continental air masses in higher elevations in northern Idaho. On the Nez Perce-Clearwater, whitebark pine is typically found above 6,500 feet elevation. Forest associates are other high-elevation species, such subalpine fir, Engelmann spruce, mountain hemlock, and subalpine larch. The spruce-subalpine fir types are home to the Canada lynx, a species listed under the Endangered Species Act that is an important associate of forests at high elevations.

Whitebark pine trees may occur in pure stands on some of the higher ridges and mountain tops. When they occur at the lower elevations within their range, they typically serve as a minor early seral species in mixed conifer stands. At the other extreme, where they are found at the uppermost elevations above 8,000 feet in rather pure stands, they can serve as a major climax species. This tree is considered a “keystone” and “foundation” species because of its significant role in subalpine ecosystems (Keane and Parsons 2010, Jenkins 2011). Whitebark pine is listed as a threatened species under the Endangered Species Act by the United States Fish and Wildlife Service to be managed under the 4(d) Rule.

Whitebark pine is susceptible to mountain pine beetle. Three outbreaks of mountain pine beetle in the northern Rockies have occurred over the past 100 years. The first outbreak, in the 1920s to 1930s, killed significant areas of whitebark pine and left many “Ghost Forests.” These snags can still be seen today.

In the past couple of decades, white pine blister rust has arrived at the high elevation sites where whitebark pine lives and has been decimating the remaining trees. There is a western-wide effort to collect seed from apparently rust-resistant trees and begin a breeding program for rust-resistant whitebark pine. Seed from this effort would be used to restore whitebark pine as opportunities arise. In addition, as wildland fire occurs, openings in the subalpine forests create opportunities for natural regeneration from remaining rust-resistant trees and for selection for rust resistance.

Several outbreaks of spruce beetle have also occurred. This beetle has a two-year life cycle and can cause significant mortality in the large tree size class with greater than 20 inches diameter at breast height. Vast areas of large diameter spruce forests do not exist, so local mortality can be high when an outbreak of spruce beetle occurs because the beetle can fly a couple miles between host trees; however, acres infested were low compared to mountain pine beetle in whitebark pine and lodgepole pine.

Old Growth

Old growth forests are ecosystems distinguished by old trees and related structural attributes. Old growth encompasses the later stages of stand development that typically differ from earlier stages in a variety of characteristics, which may include tree size, accumulations of large dead woody material, number of canopy layers, species composition, and ecosystem function (Green et al. 2011).

The 2012 Planning Rule places a strong emphasis on natural range of variation and emphasizes natural patterns and processes and integrated thinking, rather than piecemeal protections. The tack of prohibiting all actions that would modify any stands such that they would no longer meet the definition of old growth as set forth in Green et al. (2011) does not account for the historic disturbances and patterns that the 2012 Planning Rule suggests are so important. Green et al. (2011) on page 2 states:

Many of the oldest stands of old growth are dominated by seral tree species that are maintained as dominants and protected from crown fire by repeated underburns that reduce ladder fuels and competition from more tolerant tree species…the bulk of presettlement upland old growth in the northern Rockies was in the lower elevation, ground-fire maintained Ponderosa pine/Western larch/Douglas fir types.

Thus, any sideboards for managing old growth should stem from a need to be consistent with natural patterns and processes and should be developed by thinking holistically about ecosystems, rather than just a blanket protection for all forests meeting the Green et al. (2011) old growth criteria. In total, Green et al. (2011) defined nine old growth types for north Idaho. These old growth types are presented in Table 20, along with the cover types and habitat type groups associated with each old growth type. Each old growth type is discussed in terms of the disturbance regimes necessary to develop each type, with excerpts from Green et al. (2011) presented in quotes. For a complete list of habitat types and groupings, refer to Green et al. (2011).

Table 20. Relationship between old growth types, cover types, and habitat groups. Quotations are from Green et al. 2011.

Old Growth Type	Old Growth Forest Cover Types	Habitat Type Group	Group Description
1	PP, DF, L	A, B	Ponderosa pine, Douglas fir, and Western larch that occur on warm, dry environments. “Prior to 1900, cool underburns at intervals of 5 to 25 years promoted open stands, while hotter stand replacing fires occurred every 150 to more than 300 years.”
2	LP	B, C, D, E, G, H, I, J, K	Lodgepole pine forest type on cool and cold environments. “Prior to 1900, repeated fires at less than 100 to 150 years favored the occurrence of large stands of nearly pure lodgepole pine.”
3	Y	C, C1, G1	Pacific yew forest type on cool, moderately moist environments. Generally limited to the Nez Perce but may occur on the Clearwater and Idaho Panhandle Forests. “Protection from frequent fire by topographic or climatic factors is required for the occurrence of this type.”

Old Growth Type	Old Growth Forest Cover Types	Habitat Type Group	Group Description
4A	DF, GF, L, SAF, WP, PP	C, C1, D, E	Douglas fir, grand fir, Western larch, Engelmann spruce/subalpine fir, Western white pine, and Ponderosa pine forest types on warm dry and warm moist environments. “Prior to 1900, infrequent stand replacing wildfires favored development of long lived seral and climax stands on grand fir and Douglas fir sites. Spruce and subalpine fir occur primarily within riparian zones.”
4B	DF, GF, L, WH, WP, PP	F, G, G1, H, I	Douglas fir, grand fir, Western larch, Engelmann spruce/subalpine fir, western hemlock, Western white pine, and Ponderosa pine forest types on warm moist and cool moist environments. “Prior to 1900, infrequent stand replacing wildfires favored development of long lived seral and climax stands on cedar and western hemlock sites.” Ponderosa pine is maintained only on sites with frequent fire return intervals.
5	SAF, MAF	F, G, H, I	Engelmann spruce/subalpine fir, mountain hemlock/subalpine fir types on cool moist environments positioned on north to east aspects at elevations above 4,000 feet. Groups F and G are composed of western redcedar (WRC) and western hemlock (WH) series habitat types, occurring on warm moist environments along low benches and riparian zones.
6	WBP	I, J, K	Whitebark pine (WBP) forest types. “Prior to 1900, repeated fires at intervals of less than 100 to 150 years favored the occurrence of whitebark pine stands.” This old growth type only occurs within the cool/moist and cold potential vegetation type groups.
7	C	F, G, G1	Western redcedar forest type on warm moist environments. The fire return interval is generally more than 200 years with stand replacing events being dominant, which favors development of long lived seral and climax stands on these sites. These types occur in areas protected from summer drought, which indicates that this type of old growth often occurs in riparian areas, areas with a very deep ash cap, and typically wet summer precipitation pattern.
8	DF, L, SAF, MAF, WP	J	Douglas fir, Western larch, Engelmann spruce/subalpine fir, mountain hemlock/subalpine fir, and white pine forest types on cool moist and cold environments. “Prior to 1900, repeated fires at intervals of 100 to 200 years favored the occurrence of nearly pure Douglas fir, Western larch, or white pine.”
9	SAF, MAF	K	Engelmann spruce/subalpine fir and mountain hemlock/subalpine fir forest types on very cold, harsh environments. “Fire suppression since 1900 has resulted in the conversion of many stands once dominated by seral whitebark pine to ES/SAF and MH/SAF.” This type is almost completely within the cold potential vegetation type group.

Topographic position can influence the probability of old growth development; areas protected from wildfire, such as riparian areas or rock features, may support vegetation legacy components. Such forest patches that survive wildfire may be referred to as “refugia” and can represent important biological legacies that contribute to future seed and biodiversity and may eventually develop into old growth patches in an otherwise “young” forest landscape. In the high elevation subalpine zone forests, the majority of the landscape would have stand ages of over 150 years. Fire regimes are varied in the subalpine zone with a mixture of low severity fires that maintain whitebark pine stands to stand replacing events, which promote patches of subalpine fir and mountain hemlock (Arno 1980). Drier Ponderosa pine and Douglas fir types developed under a more frequent disturbance regime (Arno et al. 1995, Tesch 1981, Seidl et al. 2014, Franklin et al. 2008) characterized by frequent fire return intervals (30-100 years) with low to mixed severity fire events. Old growth patches occurring within mid elevational mesic forests are developed and influenced by both low severity and mixed severity fire occurring at frequencies less than the maximum biological age of late successional species (Agee 2007, Hessburg, Reynolds, et al. 2007, Hessburg, Salter, and James 2007). Higher elevation, cool moist habitats are often dominated by Engelmann spruce-subalpine fir and lodgepole forest cover types, which were largely established from stand-replacement events (Arno et al. 1993).

From an early successional seedling stage, it would take 150 to 200 years for a forest to become old growth. Wildfire influences old growth development. The likelihood of a particular forest stand experiencing wildfire within 30 to 150 years would be high across many parts of the forest. Therefore, long-lived, early successional, fire tolerant tree species play a critical role in the development of old growth. These trees have a chance of surviving wildfires and persisting well into the late successional stages and include Ponderosa pine, Douglas fir, Western larch, and whitebark pine. They become the large diameter, old trees that are key features of the old growth forest. Old growth dominated by shade tolerant trees, such as grand fir, western redcedar, and Engelmann spruce, also occur particularly in riparian areas or other sites protected from disturbance. These old growth types typically contain early seral species along with a dominant overstory composed of late successional species (Arno et al. 2000).

Snags and Snag Retention

Snags and snag retention were brought forward as a concern during public scoping. Developed plan components are intended to ensure the retention of the desired number of snags per unit area to provide habitat elements and to promote long-term recruitment of coarse woody debris. Dominance type affects the species of snags occurring on the landscape, as well as the duration of snags. Seral species' snags tend to remain standing for longer periods than snags derived from climax species, except for western redcedar. Size class distribution affects the size of snags occurring on the landscape. Desired conditions for size class distribution will influence the average snag diameter. Snag recruitment is affected by and influences disturbance regimes.

Tree mortality results from a host of factors. Moisture stress due to droughty conditions may cause mortality, particularly within dense stands. Stand density may promote mortality due to competition for moisture and sunlight. Small scale disturbances, such as endemic levels of insect and disease agents, are constantly causing natural levels of mortality. Wildland fire is another cause of mortality which disproportionately affects small diameter trees and can consume snags of any size.

Non-Forested Vegetation

Persistent non-forested plant communities are widespread on many of the management areas on the Nez Perce-Clearwater. These communities are maintained by site conditions that preclude establishment of trees or by frequent disturbances, such as fire. The most common communities found on the Nez Perce-Clearwater are grasslands, but wetlands, riparian areas, and alpine communities are also present. In some places, communities with grasses, forbs, and shrubs occur as a transitional type in the earliest stages of forest succession.

Non-forested vegetation communities have shifted in extent, composition, and structure but are less explicitly represented and modeled with available data than forested types. Grazing and associated reduction in fire frequency due to the loss of fine fuels are the primary causes of woodland expansion, although climate change is also suggested as a contributing factor (Hessburg and Agee 2003). Fire exclusion and drought have allowed conifers to invade grasslands and altered the mosaic of conifer savannah (Heyerdahl et al. 2006, Barrett et al. 1997). Invasive plants also are a primary threat to communities with grasses, forbs, and shrubs. Historical grazing practices have contributed to shifts to non-native species in these types to an unquantified degree. High elevation grassland or herbaceous types are less likely to be substantially altered from historic conditions because factors, such as grazing and invasive plants, are less common.

The desired condition ranges indicate the need to maintain or increase the abundance of non-forested cover types collectively on most management areas. This increase would primarily occur in the grassland types, although the maintenance of healthy riparian, wetland, and alpine areas is also important. The desired condition includes maintaining the dominance of non-forested plant communities on non-forested potential vegetation groups, as well as on some forest potential vegetation groups, primarily the driest sites found in the warm dry broad potential vegetation group. Such areas would have been maintained in a non-forested condition or one with very sparse tree cover by frequent fire. Increased conifer expansion in some of these areas is considered to be encroachment.

Xeric and Mesic Grasslands

Slope and moisture regimes divide grasslands into two general types in the plan area. The grasslands on the moister north and east facing slopes or at higher elevations are generally dominated by Idaho fescue and prairie junegrass. The grasslands on drier sites, such as lower elevation or southwest facing slopes, are dominated by Idaho fescue and bluebunch wheatgrass. Grasslands range in size from extensive canyon slopes to small patches within the forested communities to large open parks located on montane to foothill zones. Grasslands are dominated by cool-season perennial bunchgrasses and forbs with sparse shrub or tree representation. Various shrub and tree species may occur with low cover, typically less than 10 percent.

The desired condition of xeric grassland communities, such as the bluebunch wheatgrass habitat type groups, is to have vegetation dominated by native bunchgrasses while conifers are absent or occur as scattered individuals. Dominant vegetation includes bluebunch wheatgrass and Sandburg's bluegrass, along with a variety of native forbs, including arrowleaf balsamroot, lupine, phlox, and yarrow. Individual species can vary greatly in the amount of production depending on growing conditions. Plant litter is a common component and available for soil building and moisture retention. There is very little movement of plant litter off-site with natural plant mortality typically being low. Biological soil crusts are found on almost all soil types but are more commonly found in arid areas where plant cover is low and plants are more widely spaced. Bare ground is present because of the warm dry nature of these sites but at low amounts.

The desired condition of mesic grassland communities, such as fescue habitat type groups, is to have vegetation dominated by native grasses and sedges, including Idaho fescue, prairie junegrass, Sandburg's bluegrass, western needlegrass, elk sedge, Hood's sedge, and assorted native forbs, including cinquefoil, pearly pussytoes, buckwheat, biscuitroot, pinkfairies, and Geum. Biological soil crusts are found on almost all soil types while these moister habitats generally support more lichens and mosses than other types of crusts. Bare ground is typically low across most sites; plant litter is the dominant ground cover and available for soil building and moisture retention. Plant litter rarely moves off-site. Conifers are absent or occur as scattered individuals.

Xeric Shrubland/Woodlands

Xeric shrubland plant communities occur infrequently on drier sites, and the desired condition is to support shrub species, such as mountain mahogany and sumac. The understory should typically be dominated by native grass species, such as bluebunch wheatgrass, Idaho fescue, and Sandberg bluegrass. Canopy cover varies depending on the site and growing conditions but should typically be low to moderate. Xeric woodlands are typically hot and dry or are steep with shallow, skeletal soil.

Riparian/Wetland Vegetation

This section discusses the existing and desired vegetation characteristics of riparian areas and wetlands. Refer to the Water Resources section for information on the hydrologic function of riparian areas and wetlands and the Aquatic Ecosystems and Fisheries section for information pertaining to the relationship of riparian vegetation with the aquatic biota.

Riparian systems occur along creeks and rivers and occupy floodplains, streambanks, islands in rivers, narrow bands in steep channels, and backwater channels. This system is dependent on a hydrologic regime that has annual to episodic flooding. Riparian vegetation should be comprised of a mosaic of plant communities dominated by species which tolerate periodic flooding and an associated seasonally high-water table. Trees may be present along with riparian shrubs and herbaceous species. In wide valley bottoms, the vegetation typically should be a mosaic of all lifeforms with patterns reflecting the meander patterns of the stream or river. Key tree species include aspen, cottonwood, Engelmann spruce, and subalpine fir; on drier sites, Douglas fir and Rocky Mountain juniper may be present. Dominant shrubs may include mountain alder, various species of willows, river birch, dogwood, hawthorn, chokecherry, rose, silver buffaloberry, Rocky Mountain maple, and snowberry. A wide variety of herbaceous species, including grasses, sedges, rushes, spikerushes, bulrushes, and forbs, should be present in the understory. Threats to the riparian system include heavy grazing, invasive species, road construction and maintenance, drought, recreation, and climate change.

Wetlands are characterized by dominant vegetation adapted to saturated anaerobic soil conditions. The vegetation complex should be represented by a mosaic of herbaceous and woody plant communities that provide excellent erosion control. Low willow species, bog birch, and bog blueberry are often the representative woody species in a wetland system. Herbaceous species may be dominated by cattails, sedges, rushes, spikerushes, or bulrushes. Bryophytes, including sphagnum, are often well represented in fens. Threats to wetlands include alteration of the original hydrology or hydric soils, such as diversion, draining, development, road construction, and heavy grazing; invasive species; and climate change.

Willows (*Salix* spp.) are of particular importance in riparian and wetland plant communities. Willows require a seasonally high-water table and free water in the soil to survive and regenerate. Most species are shade-intolerant and those species that occur along streams in narrow steep valleys will likely not persist if conifers overtop them. Browsing pressure by both native and domestic ungulates can lead to reduced density and vigor of willow stands. Coyote willow regenerates vegetatively; all other willows germinate successfully in bare, moist, mineral substrate stream bars. Regeneration is less likely to occur on other substrates. There are two main categories of willows.

Tall willows, including various species of tall-stature typically up to 20 to 30 feet tall, occur along streams in broad valley bottoms at low- to mid-elevations. They occur as a mosaic with various other riparian shrubs, graminoids, and forbs in the understory, forming a riparian complex. Tall willow species include, but are not limited to, Booth's (*Salix boothii*), geyer (*S. geyeriana*), bebb (*S. bebbiana*), coyote (*S. exigua*), drummond (*S. drummondiana*), and whiplash (*S. lasiandra*) willow.

Low willows, including low-statured willows typically up to 4 feet tall occur in higher elevation valleys, usually associated with subalpine forests. They occur as a riparian strip along streams and as a complex either associated with sinuous streams or in wet meadows or fens in wide, flat valleys associated with standing water. Low willow species include, but are not limited to, planeleaf (*S. planifolia*), wolf (*S. wolfii*), and mountain (*S. eastwoodiae*) willow. Bog birch (*Betula pumila*) and bog blueberry (*Vaccinium uliginosum*) may also be present in the low willow complex. Riparian or wetland graminoids and forbs are typically present in varying amounts and can be present with high cover in a low willow or herbaceous vegetation mosaic or riparian or wetland complex.

Aggressive fire suppression over the last 100 years, coupled with implementation of the PACFISH and INFISH amendments to the existing forest plans in 1995, has greatly reduced natural disturbance regimes within riparian systems. Forest succession in the absence of disturbance, particularly wildland fire, has resulted in encroachment of conifer species into much of the riparian system. Conifer species have replaced much of the tall woody species, such as willows, cottonwood, and birch. Only tolerant hardwood species are generally present. Restoration of natural fire regimes would reestablish tall hardwood components and help to maintain a mosaic of vegetation patterns which are important for a wide variety of wildlife species.

Alpine and Rocky Habitats

Alpine and subalpine ecosystems occupy harsh high elevation sites, resulting in short stature and relatively slow growth for trees, shrubs, and herbaceous species. Wetland communities are present in snowload depressions and support various willow species, along with wetland herbaceous species. Alpine ecosystems are mostly treeless, although some conifers may be present with minor cover, often with a krummholz growth form. Vegetation cover should typically be low to moderate. The non-forested plant communities are dominated by several shrubs, forbs, and graminoids, including arctic willow (turf community), mountain avens (cushion plant community), mountain heather, and moss-heather (snow bed communities).

Rocky habitats are often associated with the alpine potential vegetation type, including rock outcrops and scree. Vegetation is sparse or largely lacking. Bryophytes and lichens often occur in crevices and flourish on open rock surfaces where the competition from vascular plants is absent. Rock outcrop and scree habitats may also be found at lower elevations. Rocky habitats are often fragile systems.

Xeric Ecotones and Savannas

Ecotones are the boundaries between ecosystems or biomes (Allen and Breshears 1998). These areas are often sparsely vegetated and occupy the fringes of adjacent systems. On the Nez Perce-Clearwater, the xeric ecotone represents the transition from non-forested xeric grass and shrub communities to dry forest communities. Scattered trees and shrubs, including Ponderosa pine, Douglas fir, and mountain mahogany, may be common. Species composition can vary, depending on the moisture regime and adjacent communities. Xeric ecotones are complex because they overlap forested and non-forested potential vegetation types. The plant communities found may shift between grass, shrub, and conifers based on climate and disturbances (mainly fire). Depending on the vegetation composition and structure, these areas may be typed as non-forested cover types or possibly the Ponderosa pine or Douglas fir cover type where substantial cover of conifers has established.

Savannas are a particular forest structure within xeric ecotones. For this analysis, savannas are defined as communities found on either non-forested or the warm dry broad potential vegetation group, which contain very open tree cover (5-10 percent canopy cover) and an overall dominance of xeric grasses or shrubs. Savannas are likely to be found on the hottest, driest sites in the warm dry broad potential vegetation group. Historically, frequent fire would have maintained the dominance of grasses and shrubs while promoting the development of very large widely scattered individual or patches of Ponderosa pine or Douglas fir, limiting the establishment of small conifers. However, fire exclusion has resulted in the shift of some of these areas to more densely forested areas, often with the development of Douglas fir ladder fuels, a decrease in grass and shrub vigor, and an increase in crown fire potential. As this occurs, the large, old trees of the savannah become vulnerable to mortality from uncharacteristic fire effects or insect infestations.

It is desirable to promote the open character of forest savannahs and a dominance of grass and shrub communities in most xeric ecotones, particularly given expected future warm and dry climate conditions. Due to limitations in available data sources and modeling tools, the overall desired extent of these plant communities is encompassed within the desired range of non-forested cover types. For additional information on existing condition of rangelands, including grasslands and meadows, see the Livestock Grazing section.

Existing and Desired Condition by Management Area

This section describes the existing condition for each ecological component used for analysis within this report. These ecological components include vegetation composition, size class distribution, density, landscape resilience, rare and unique habitat elements, and old growth. Vegetation composition is described by dominance type and size class distribution. Forest density is described by canopy cover. Resilience is described with a combination of three elements including insect and disease hazard ratings, projected wildland fire, and vegetation patch size. Together, these three elements describe the degree to which current forest conditions are departed from natural range of variation and the current resiliency of the forest to natural disturbances. Rare and unique habitat elements are described qualitatively in the context of current and desired abundance and distribution of quacking aspen. Old growth is also described qualitatively in terms of the current and desired percentage and distribution of old growth types found on the Nez Perce-Clearwater.

Each of these components is discussed in turn and are described for each management area and broad potential vegetation type group. These components are expected to change over time in the absence of management and in responses to proposed management regimes. Each proposed alternative will have varying effects on each of these components.

Management Area 1

Dominance Type

The dominance types in Management Area 1 are displayed in the following tables compared with the ranges for desired conditions, given as a percentage of Management Area 1. For the current conditions, Management Area 1 is equated to wilderness. While there may be small acreage differences between the Management Areas in the various alternatives, the existing condition is shown by currently delineated areas that are not expected to change to give a consistent picture of conditions among all alternatives, rather than having fluctuations due to changing delineations of where boundaries are drawn.

Table 21. Current and desired dominance types within the Cold potential vegetation type in Management Area 1.

Dominance Type	Current Condition1	Desired Range
Lodgepole pine	28%	30–40%
Subalpine fir/Engelmann spruce	35%	3–10%
Whitebark pine	0%	35–50%
Douglas fir/Western larch	4%	0–5%
Mountain hemlock	0%	2–5%
Seral stage grass/shrub	23%	5–15%

1Current condition is based on the proportion of the potential vegetation type group and management area that is classified as a “tree” lifeform. The total does not sum to 100 percent due to rounding and some nondescript classifications, such as “intolerant mix.”

Table 22. Current and desired dominance types within Cool Moist potential vegetation type in Management Area 1.

Dominance Type	Current Condition[1]	Desired Range
Douglas fir	7%	2–4%
Lodgepole pine	10%	20–30%
Western larch	0%	5–10%
Douglas fir/Western larch	1%	1–2%
Grand fir/mountain hemlock	1%	1–2%
Western white pine	0%	5–10%
Subalpine fir/Engelmann spruce	53%	25–40%
Whitebark pine	0%	2–10%
Seral stage grass/shrub	28%	5–25%

[1]Current conditions are based on the proportion of the potential vegetation type group and management area that is classified as a "tree" lifeform. The total does not sum to 100 percent due to rounding and some nondescript classifications, such as "intolerant mix."

Table 23. Current and desired dominance types within Warm Dry potential vegetation type in Management Area 1.

Dominance Type	Current Condition[1]	Desired Range
Ponderosa pine	16%	50–60%
Douglas fir	25%	15–20%
Lodgepole pine	3%	5–12%
Western larch	0%	1–2%
Douglas fir/Western larch	4%	0–2%
Grand fir	22%	5–15%
Seral stage grass/shrub	28%	2–10%

[1]Current conditions are based on the proportion of the potential vegetation type group and management area that is classified as a "tree" lifeform. The total does not sum to 100 percent due to rounding and some nondescript classifications, such as "intolerant mix."

Table 24. Current and desired dominance types within Warm Moist potential vegetation type in Management Area 1.

Dominance Type	Current Condition[1]	Desired Range
Ponderosa pine	0%	5–20%
Douglas fir	28%	5–10%
Lodgepole pine	0%	1–2%
Western larch	0%	5–10%
Douglas fir/Western larch	4%	5–10%
Grand fir/western redcedar	61%	15–25%
Western white pine	0%	10–20%
Subalpine fir/Engelmann spruce	2%	0–2%
Grand fir	43%	10–20%
Early Seral stage grass/shrub	5%	5–20%

[1]Current conditions are based on the proportion of the potential vegetation type group and management area that is classified as a "tree" lifeform. The total does not sum to 100 percent due to rounding and some nondescript classifications, such as "intolerant mix."

Size Class Distribution

The size class distributions within Management Area 1 are displayed in the following tables compared with the ranges for desired conditions given as a percentage for each size class. All size classes sum to 100 percent because each class is represented as a percent of all size classes represented within Management Area 1. Each size class distribution table is summarized by potential vegetation type group to facilitate comparisons across alternatives.

Table 25. Current and desired size class distribution for Cold potential vegetation type group in Management Area 1.

Size Class	Current Condition	Desired Range
Seral grass or shrub	27%	5–20%
0–4.9” DBH	6%	15–30%
5–9.9” DBH	33%	5–25%
10–14.9” DBH	26%	5–15%
15–19.9” DBH	6%	25–50%
20” + DBH	2%	0–5%

Table 26. Current and desired size class distribution for Cool Moist potential vegetation type group in Management Area 1.

Size Class	Current Condition	Desired Range

Management Area 2

Dominance Types

The dominance types in Management Area 2 are displayed in the following tables compared with the ranges for desired conditions, given as a percentage of Management Area 2. For the current conditions, Management Area 2 is equated to Idaho Roadless Areas (IRAs) and the Forest Inventory and Analysis classification of Other Protected/Administrative Areas (OPAAs). While there may be acreage differences between the Management Areas in the various alternatives, the existing condition is shown by currently delineated areas that are not expected to change to give a consistent picture of conditions among all alternatives, rather than having fluctuations due to changing delineations of where boundaries are drawn.

Table 29. Current and desired dominance types within Cold potential vegetation type group in Management Area 2.

Dominance Type	Current Condition[1]	Desired Range
Lodgepole pine	34%	30–35%
Subalpine fir/Engelmann spruce	26%	5–15%
Whitebark pine	2%	35–50%
Douglas fir/Western larch	0%	0–5%
Mountain hemlock	22%	0–5%
Seral stage grass/shrub	16%	5–15%

[1]Current conditions are based on the proportion of the potential vegetation type group and management area that is classified as a “tree” lifeform. The total does not sum to 100 percent due to rounding and some nondescript classifications, such as “intolerant mix.”

Management Area 3

Dominance Types

The dominance types in Management Area 3 are displayed in the following tables compared with the ranges for desired conditions, given as a percentage of Management Area 3. For the current conditions, Management Area 3 is equated to lands managed for multiple uses including timber production within the constraints of forest practices regulations, laws, and special management restrictions. All areas suitable for timber production are within Management Area 3. While there may be acreage differences between the management areas in the various alternatives, the existing condition is shown by currently delineated areas to allow comparison among all alternatives.

Table 37. Current and desired dominance types within Cold potential vegetation type group in Management Area 3.

Dominance Type	Current Condition[1]	Desired Range
Lodgepole pine	56%	30–40%
Subalpine fir/Engelmann spruce	26%	3–10%
Whitebark pine	0%	35–50%
Douglas fir/Western larch	6%	0–5%

Size Class Distributions

The size class distributions within Management Area 3 are displayed in the following tables compared with the ranges for desired conditions given as a percentage for each size class. The grass or forb and 0–4.9” diameter at breast height size classes are maintained as distinct size classes within Management Area 3. This recognizes the need to maintain desired stocking levels on lands suitable for timber production, as well as the need to allow for temporary openings to achieve wildlife management objectives. Openings within the forested canopy may still be maintained to promote other resource objectives as suggested by the broad range of desired conditions for this size class. All size classes sum to 100 percent because each class is represented as a percent of all size classes represented within Management Area 3. Each size class distribution table is summarized by potential vegetation type group to facilitate comparisons across alternatives.

Large-tree Structure

Large-tree structure, as defined in Appendix B of the Land Management Plan, identifies where large and very large trees are present in sufficient numbers to contribute to key ecosystem processes. This large-tree structure metric may be quantified as having large trees (15-19.9" DBH) only, very large trees (20+" DBH) only, or both large and very large trees concurrently. Large-tree structure may occur within any forest size class. Based on forestwide Forest Inventory and Analysis (FIA) data, a large-tree structure is found in 0 percent of the seed or sap class; 10 percent of the small tree class; 36 percent of the medium tree class; 26 percent of the large tree class; and 12 percent of the very large tree class. Given the high level of productivity associated with most of the forested areas of the Nez Perce-Clearwater, areas of the forest meeting large tree structure criteria are common. Areas of the forest meeting the “Both” structural criteria are more meaningful in terms of legacy trees, genetic refugia, and wildlife habitat components. Based on forestwide FIA data, the Both (large tree and very large tree) structure is found in 0 percent of the seed or sap class; 1 percent of the small tree class; 15 percent of the medium tree class; 49 percent of the large tree class; and 61 percent of the very large tree class. Desired conditions are not expressly derived for the large tree structure attribute within the Land Management Plan. Plan components FW-DC-FOR-05, 08, and 11 express the desired condition of having legacy tree components to be distributed among all size classes present on the forest. As Table 45 illustrates, there is an opportunity to incorporate large tree structure within the seedling and sapling size classes. SIMPPLLE does not track these classes explicitly. However, as discussed in the size class section, this attribute can be directly compared to the SIMPPLE natural range of variation outputs for large and very large tree size classes.

Table 45. Large tree structure distribution among size classes.

Size Class	Large	Both (Large and Very Large)	None
Seedling	0%	0%	100%
0.1–4.9” DBH	0%	0%	100%
5.0–9.9” DBH	10%	1%	89%
10.0–14.9” DBH	36%	15%	49%
15.0–19.9” DBH	26%	49%	25%
20.0–24.9” DBH	12%	61%	27%
25+” DBH	8%	59%	33%

Large-tree Structure does not total 100 percent due to inclusion of non-forest areas.

Data Source: R1 Summary Database 2015 Hybrid dataset.

Current and Desired Conditions Common to All Management Areas

Density

Desired conditions for forest density classes are informed by the natural range of variation (NRV) analysis and enumerated in the following table. Vertical structures are discussed through narrative description. These desired conditions would not necessarily apply to the No Action Alternative but are included in the analysis for all alternatives to provide for a comparison.

Table 46 displays the current forestwide proportions of forest density classes compared to the natural range of variation. An array of density classes across the landscape would contribute to desired ecological, social, and economic conditions. Forest density influences wildlife habitat, forest resilience, timber productivity, and crown fire potential. More open densities tend to be more resilient to fire, as well as insects and diseases, and promotes the growth of large trees. Moderate densities tend to maximize timber production. Higher densities provide valuable wildlife habitat conditions particularly in the warm moist broad potential vegetation group. The desired conditions, based on the natural range of variation, indicate that low to medium and medium to high forest densities are below the desired range, and the abundance of high density is above the desired range.

Table 46. Forestwide canopy cover percentage by tree density class.

Tree Density Class	Canopy Cover Range	Forest-wide Existing Condition	Natural Range of Variation
Non-forested	<10%	23%	16%
Low to Medium	10–39.9%	25%	49%
Medium to High	40–59.9%	52%	35%

Data Source: R1 Summary Database 2015 Hybrid dataset.

The natural range of variation analysis indicated that the low to medium canopy cover class was common forestwide, especially on the warm dry broad potential vegetation group. Fire exclusion has resulted in higher canopy densities across all potential vegetation type groups which would otherwise have been maintained at more open densities by frequent low intensity fire. Many forests on the cool moist sites also had low to medium density, which were likely forests in their early and mid-successional stages or older forests where disturbances removed trees and opened the canopy. In all types, the shift toward higher densities reflects the impacts of fire exclusion and the increased abundance of shade tolerant species. Low to medium density forests were at the higher end of their natural ranges during warm dry periods, whereas medium-high and high-density forests were at the lowest end. In pine dominated forests, the mountain pine beetle may cause changes in the forestwide averages. It is likely that some of the high-density Ponderosa pine areas may shift into open classes because of the combined effects of pine beetle and wildfire. In lodgepole pine systems, the combination of mountain pine beetle caused mortality and wildfire may reduce stand density in the short term but has a greater effect on stand structural class. Lodgepole pine stands may shift from a high-density stem exclusion stage into a high density stand initiation stage.

Figures found in Appendix B also display the current proportions of vertical structure classes compared to the natural range of variation. There are no desired conditions developed specifically for this attribute. Single-storied forests are more common than they were historically, while multi-storied forests are less common, especially in the warm dry and cold broad potential vegetation types. The cool moist potential vegetation type appears to be within the natural range of variation for all vertical structure classes.

Areas with less than 10 percent canopy cover are considered non-forested. This class may include open forest savannas or persistent grass or shrub communities that occur on the cold and warm dry broad potential vegetation groups. Such sites may have multiple age classes but large, fire resistant, and drought tolerant trees such as Ponderosa pine are favored. This class also includes areas on any potential vegetation type that has been recently de-forested through disturbance and trees have not yet re-established. Finally, true non-forested communities are included (grasslands, riparian or wetlands, and alpine communities).

Low and medium tree canopy cover classes represent relatively open forests with 10 to 39.9 percent canopy cover. This class is common in young forests. In addition, low densities are found in dry forest types at all stages of succession, particularly in the warm dry broad potential vegetation group, where site conditions or disturbances maintain low tree density. Cool moist or cold forests may also be in this condition particularly where they are impacted by disturbances such as mountain pine beetle infestations or wildland fire.

The medium to high tree canopy cover class represents a more fully stocked forest, a condition which is common in more moist forests of shade tolerant species, often found on the cool moist and warm moist broad potential vegetation groups. Examples of forests with this density could include mature single-storied lodgepole pine or spruce or fir multistoried stands. Dry forests may also be in this density class particularly where fire has been excluded and understory layers have developed.

The high canopy cover class includes forests with a relatively closed canopy, most often on productive sites on the cool moist broad potential vegetation group. This density class is common in stands with a spruce or fir component in a multi-storied condition. This condition also arises in single-storied lodgepole pine and sometimes Ponderosa pine or Douglas fir that regenerate to extremely high densities after fire. High tree density can limit tree growth as well as sunlight to the understory, limiting vegetation in the understory. This condition may also occur in dry forests that have missed natural fire entries and developed layers in the understory.

Landscape Resilience

The spatial pattern of vegetation can affect ecological processes, including wildlife and plant habitat and dispersal; disturbance risk, spread, and size; reforestation; watershed health; carbon storage; wildlife habitat quality; and aesthetic values. Connectivity can be affected by natural factors such as topography, soils, variation in precipitation, and wildfire but also by human developments and activities. It is also one of the most complex attributes of ecosystems to quantify. The goal of assessing connectivity and pattern is to better understand the mosaic of conditions that make up a resilient landscape.

Heterogeneity is the quality of consisting of dissimilar elements, as with mixed habitats or cover types occurring on a landscape. Heterogeneity on forest landscapes may occur as mosaics of patches generated by many events, but also may be created by single large events that occur infrequently (Kashian et al. 2005). The ecological, social, and economic values that forests provide are heavily influenced by spatial patterns on the landscape (Turner et al. 2013). Connectivity and pattern also influence the genetic flow of plant material, which has implications for the adaptability of vegetation. Seed dispersal strategies will depend on spatial heterogeneity and the suitability of future site conditions. Maintaining a robust genetic base is a primary foundation of resilience.

Generally, a resilient landscape is made up of a mosaic of age classes, composition, and successional stages because this ensures that not all areas are equally susceptible to the same drivers, such as wildfire and insects, at the same time. For example, homogeneous large areas of dense forests can create higher potential for large, high severity fire. The spread of wildfires and the potential for large fire growth can be limited by reducing fuel continuity (Ager et al. 2010, Collins et al. 2009, Finney et al. 2007, Finney 2003, Hessburg, Reynolds, et al. 2007, Safford et al. 2009, Stephens et al. 2009). Large landscapes where wildfires have been allowed to burn can develop such fuel heterogeneity; therefore, future fires could be limited in size relative to landscapes that have more homogeneous fuels (Bollenbacher 2010, Collins et al. 2009, Rollins et al. 2002, Van Wagtendonk 2004). Similarly, large expanses of forests with susceptible characteristics can create higher potential for bark beetle outbreaks (Fettig et al. 2007, Samman and Logan 2000). For bark beetles, the severity of outbreaks and tree mortality can be reduced in extent by increasing the diversity of stand ages, size classes, and tree species (Bentz et al. 2010, Fettig et al. 2007).

It is impossible to effectively model and analyze all the possible metrics of landscape pattern, or to capture all of those that would be meaningful for the variety of wildlife species in the plan area. The abundance, average, and range of sizes of early successional forest patches (transitional and seedling or sapling size classes) have been identified as the key ecosystem characteristics to represent landscape pattern because this condition is quantifiable, represents likely patterns of older forests, and is meaningful for many species. Openings in the forest are created after a stand-replacing disturbance and are the most distinct and easily detectable structural conditions in a forested landscape because they are dominated by grass, forbs, shrubs, and short trees. They are meaningful to many wildlife species because of their distinctive composition and openness, which affects the growth and survival of plants that wildlife depends on, and strong contrast to adjacent mid or late successional forest ("edge"). They also represent the initiation point in forest development, the foundation upon which rests the pattern of the future forest.

Results of the natural range of variation analysis were used to inform the desired conditions for earlier successional forest patches (Table 47). Refer to the document "Using Natural Range of Variation Modeling to Estimate Historic Opening Size on the Nez Perce-Clearwater National Forests" found in the project record for a detailed discussion of opening size calculations. An eighteen-acre filter was used to remove polygons less than 18 acres is size. The three indicators used are:

Average patch size, which is a simple arithmetic mean of cumulative area of patches divided by the number of patches; and

Area weighted mean patch size, in which the mean is weighted based on the proportion of the area of patches relative to the total. This metric indicates whether there are large patches in the landscape, or if most patches are close to the average. For example, in a forest with a 99-acre patch and a 1-acre patch, the average size is 50 acres, and the area-weighted mean is (99*0.99 + 1*0.01) 98.02 acres.

Jenks Natural Breaks Distribution: This algorithm arranges opening size values into logical size classes that minimize the within-class variance while maximizing the between-class variance.

An opening was included in the calculation for as long as it remained in the seedling or sapling size class. This provides the full ecological picture of the extent and duration of forest openings. A patch analysis was also run to inform the development of timber standards related to maximum opening sizes that can be created with even-aged timber harvest; refer to Appendix B and the Timber section.

Table 47. Early successional forest patch size acres by broad potential vegetation group, existing condition, and natural range of variation.

Broad Potential Vegetation Group	Existing Condition-Mean. Patch Size (acres)	Existing Condition-Area Weighted Mean of Patch Sizes (acres)	Natural Range of Variation-Mean Patch Size of Patches (acres)	Natural Range of Variation-Area Weighted Mean Patch Size (acres)
Forestwide	79	736	350	28,207

Broad Potential Vegetation Group	Existing Condition-Mean. Patch Size (acres)	Existing Condition-Area Weighted Mean of Patch Sizes (acres)	Natural Range of Variation-Mean Patch Size of Patches (acres)	Natural Range of Variation-Area Weighted Mean Patch Size (acres)
Cold	31	124	95	1,094
Cool Moist	59	390	188	6,579
Warm Dry	35	95	77	1,442
Warm Moist	54	331	160	9,536

Data Source: Existing condition and natural range of variation data from SIMPPLLE

Historically, there was rarely, if ever, a decade when there were not openings created by fire somewhere on the Nez Perce-Clearwater. The majority of fires were relatively small (as indicated by the arithmetic average). However, when the big fires did occur, they were very large (as indicated by the area weighted mean). These large fires would typically be associated with warm climatic periods and drought conditions.

The natural range of variation (NRV) for patch sizes on the Nez Perce-Clearwater helps to inform the desired condition for patch sizes and the relative distribution of patches within a given potential vegetation type group. The forestwide existing condition of patch sizes is well below the natural range of variation range. Each broad potential vegetation group has calculated means below the natural range of variation average means, as well as area weighted means which are very departed from the natural range of variation ranges. These differences between existing means and natural range of variation means are directly related to fire suppression over the last century and limitations on maximum patch size allowed for even-aged silviculture treatments. The decrease in mean patch size at the broad potential vegetation type group level has increased fragmentation. Early successional patches in the warm dry and cold broad potential vegetation groups are smaller than in cool moist and warm moist, due to a more frequent low severity disturbance regime which causes a complex mosaic of within-stand structures including small patches and canopy openings. Patches in the warm moist and cool moist broad potential vegetation group tend to be larger, due to a preponderance of lodgepole pine and infrequent, high severity disturbances. The largest patch sizes are correlated with warm dry climate periods.

Insect and Disease Hazard Ratings

There are five insect and disease factors that are considered for describing the effects these agents have on forest health and overall forest resiliency (Table 48). These factors have been developed after consultation with various members of the Forest Health Protection group, primarily Joel Egan, a Forest Entomologist, from the Northern Region Regional Office in Missoula, Montana; Daniella Malesky, a Forest Entomologist from Forest Health Protection in Coeur d' Alene, Idaho; and Christy Cleaver, a Plant Pathologist in Coeur d' Alene, Idaho. Risk factors are based on hazard and potential for occurrence, rather than actual occurrence of insects.

For the insect factors, mountain pine beetle was assessed using Egan's GIS layer that shows severe outbreak probability for mountain pine beetle. It has been vetted and offers extremely accurate predictions. For Douglas fir beetle, the Douglas fir beetle Hazard Rating map is used. This combined beetle risk rating methodology provides a coarse filter approach for assessing beetle risk across all potential vegetation type groups and can be described for each Management Area. Spruce beetle and spruce budworm status are also presented in Table 48.

For consideration of root disease, the best tool to use would be Blakey Lockman's (Pacific Northwest Region, Regional Plant Pathologist) root disease hazard rating map (Lockman and Kearns 2016). Christy

Cleaver talked with Blakey Lockman about using this and their joint recommendation was to give equal priority to those areas with moderate and high ratings on the map. While there is value in considering other diseases, there is a lack of tools to be able to do this effectively. Root disease is, by far, the most significant disease affecting current and desired dominance types.

The combined insect and disease hazard rating factor includes mountain pine beetle, Douglas fir beetle, and root disease hazards. Each is given equal weight for describing the overall impact these agents have on forest resiliency and suggests a priority for silvicultural treatment.

Table 48. Existing insect and disease hazard rating by broad potential vegetation type (PVT).

Existing insect and disease hazard rating by broad PVT	PTV Effect %	PTV Effect %	PTV Effect %	PTV Effect %
Mountain Pine Beetle (PP and LP Combined)	**None**	**Low**	**Medium**	**High**
Cold PVT	36%	37%	20%	7%
Cool Moist PVT	48%	20%	21%	10%
Warm Dry PVT	60%	11%	17%	12%
Warm Moist PVT	81%	9%	8%	3%
Douglas fir Beetle	**None**	**Low**	**Medium**	**High**
Cold PVT	83%	14%	3%	0%
Cool Moist PVT	80%	7%	9%	3%
Warm Dry PVT	47%	32%	17%	5%
Warm Moist PVT	46%	25%	22%	7%
Spruce Beetle	**None**	**Low**	**Medium**	**High**
Cold PVT	75%	21%	3%	0%
Cool Moist PVT	49%	28%	15%	7%
Warm Dry PVT	90%	7%	3%	0%
Warm Moist PVT	83%	11%	6%	1%
Spruce Budworm	**None**	**Low**	**Medium**	**High**
Cold PVT	47%	18%	23%	12%
Cool Moist PVT	31%	16%	22%	31%
Warm Dry PVT	54%	15%	22%	9%
Warm Moist PVT	51%	12%	24%	12%
Root Disease	**None**	**Low**	**Medium**	**High**
Cold PVT	70%	24%	4%	4%
Cool Moist PVT	53%	34%	13%	13%
Warm Dry PVT	60%	31%	6%	6%
Warm Moist PVT	37%	45%	17%	17%

Data Source: R 1 Summary Database, R1_Hybrid_2015.

Trends for each insect and disease agent are similar in proportion across hazard ratings (Table 48). Insect and disease agents are predominantly rated as low risk. Variations in the abundance of host species within each potential vegetation type group is the primary factor driving the medium and high-hazard ratings. For root disease, the highest percentages for medium and high-hazard ratings are associated with the warm moist potential vegetation type group. Douglas fir and grand fir are the species associated with the highest rates of root disease infection and is also the species comprising the largest percentage of species composition within this group.

The mountain pine beetle follows a similar pattern, with the largest proportion of acres having a low hazard rating. One notable exception is the cold potential vegetation type group. Only 48 percent of this group has a low hazard rating and averages 26 percent of medium hazard and over 25 percent high hazard. This is due to the composition of lodgepole pine in this group.

The Douglas fir beetle again follows the typical pattern of most acres having a low-risk hazard rating and a smaller proportion of medium and high-risk ratings. The warm dry potential vegetation type group has the largest percentage of both medium (27 percent) and high (3 percent) hazard ratings. This reflects the abundance and distribution of Douglas fir within this group.

Projected wildfire may also be used to describe the degree of departure from fire regimes associated with each potential vegetation type group. Fire regimes function within the natural range of variation concept. For the Nez Perce-Clearwater, the forested landscape is composed of approximately 22 percent warm dry, 38 percent warm moist, 23 percent cool moist, and 12 percent cold broad potential vegetation types. All these types are composed of varying ratios of fire regime groups.

For example, the warm moist potential vegetation type group is composed of approximately 82 percent Fire Regime Group III, while the cool moist potential vegetation type group is composed of only 28 percent of Fire Regime Group III. As discussed previously, each fire regime group exhibits different ratios of low, mixed, and high severity fire. Differences in fire severity between fire regime groups and the differences between the ratios of fire severity between broad potential vegetation type groups gives rise to differences between existing conditions on the landscape and desired conditions informed by the natural range of variation.

Table 49 presents the existing number of acres burned per decade by each broad potential vegetation type group, compared to the natural range of variation mean average of acres burned by severity class. The warm dry potential vegetation type group is currently experiencing only 42 percent of mixed severity fire and 34 percent of high severity fire that would be expected under a naturally functioning ecosystem. For the warm moist potential vegetation type group, most of which is within Management Area 3, the level of departure is 64 percent for mixed severity and 62 percent for high severity fire. This is largely due to fire suppression within this potential vegetation type group. The cool moist potential vegetation type group exhibits a difference in fire severity types with a deficit of 24 percent for mixed severity fire and an excess of high severity fire. This is due in part to a high percentage of this potential vegetation type group occurring in wilderness areas where fire suppression is absent or in roadless areas where fire suppression is limited. Similarly, the cold potential vegetation type group exhibits a surplus of both mixed severity and high severity fire due to most of these acres occurring in either wilderness or roadless areas of the Nez Perce-Clearwater. The cool moist and cold potential vegetation type groups are generally higher elevation sites, which are more affected by drought than lower elevation sites. Many high elevation sites experienced droughty conditions between 2015 and 2017 with a corresponding increase in fire.

Table 49. Comparison of existing and projected wildland fire per decade by fire regime and broad potential vegetation type. NRV = natural range of variation analysis.

Broad Potential Vegetation Type	Existing Mixed Severity Fire	NRV projected Mixed Severity Fire
Warm Dry	21,525	37,241
Warm Moist	22,873	64,325
Cool Moist	29,626	38,933
Cold	30,068	20,313
Broad Potential Vegetation Type	**Existing High Severity Fire**	**NRV projected High Severity Fire**
Warm Dry	16,643	25,132

Broad Potential Vegetation Type	Existing Mixed Severity Fire	NRV projected Mixed Severity Fire
Warm Moist	16,430	43,409
Cool Moist	30,934	26,274
Cold	32,028	13,708

Rare and Unique Habitat Elements

Quacking aspen (*Populus tremuloides*) is poorly distributed and represented on the Nez Perce-Clearwater. The Forest Inventory and Analysis Summary Database indicates that less than 1 percent of the forested area is composed of the aspen cover type. Abundance and distribution of aspen on the Nez Perce-Clearwater is poorly understood and represented in literature. On the Nez Perce-Clearwater, aspen is most commonly associated with the cool moist and warm moist broad potential vegetation type groups. There are no known climax stands of aspen on the Nez Perce-Clearwater, indicating that aspen on this forest is primarily a seral component following disturbance.

Aspen is dependent on wildland fire as the disturbance regime required for regeneration. Fire suppression and associated forest succession has likely reduced aspen presence during the last half century (Keyser et al. 2005, Shinneman et al. 2013). As canopy density of conifers has increased and shifted from seral conifer components to climax conifer components the presence of aspen has declined.

The desired conditions for dominance types presented in the plan would improve conditions for successful regeneration of existing aspen clones following wildland fires. There is no defined metric for tracking the success of aspen recruitment following proposed management actions or natural disturbance. As a proxy for improved forest conditions for aspen presence, the dominance types and size class objectives will likely improve conditions for aspen success and persistence. The persistence of aspen is dependent upon management regimes which attempt to mimic the natural range of variability for wildland fire.

In addition to aspen, there are several other rare and unique tree species present on the Nez Perce-Clearwater. Paper birch (*Betula papyrifera*) occupies areas typified as riparian within the cool moist and warm moist potential vegetation type groups. The ecology of paper birch is like that of aspen. It requires periodic disturbance to reduce overstory competition from conifer species to successfully reproduce. At higher elevations primarily within the cold potential vegetation type group, subalpine larch (*Larix lyallii*) is another rare species on the Nez Perce-Clearwater. This timberline species is poorly represented in part due to the limited ecotone and in some measure fire suppression. As with aspen and paper birch distribution of dominance types which allow for the reintroduction of fire is likely to promote the persistence of subalpine larch.

Old Growth

The distribution of estimated old growth forest varies across the Nez Perce-Clearwater as a function of varying distributions of broad potential vegetation types, land use allocations, and disturbance history. Based on estimates derived from the R1 Summary Database Hybrid 2015 dataset, about 11 percent of the Nez Perce-Clearwater is characterized as meeting minimum screening criteria for old growth forest. This equates to about 400,000 acres of potential old growth forest. Estimates derived from Forest Inventory and Analysis data contained in the R1 Summary Database, Hybrid 2015 dataset are not spatially explicit relative to location but do represent statistically sound estimates of old growth presence on the Nez Perce-Clearwater (Bush et al. 2018).

Table 50 compares forestwide estimates of old growth for each management area. Management Area 3 has the largest relative percentage of old growth forest cover types due to a larger percentage of this management area occurring within the warm moist potential vegetation type group and fire suppression over the last 100 years.

Table 50. Distribution of old growth forest cover types by management area.

Management Area	Estimated Old Growth Cover	Confidence Interval Low (90%)	Confidence Interval High (90%)
Forestwide	11%	9%	12%
Management Area 1	12%	9%	15%
Management Area 2	8%	5%	11%
Management Area 3	13%	10%	16%

Source: R1 Summary Database, FIA Hybrid 2015 dataset.

As discussed above, the spatial distribution of old growth forest cover types is highly influenced by the distribution of broad potential vegetation types. Table 51 illustrates the relative distribution of old growth as a function of potential vegetation type group. Fire regimes vary with potential vegetation type group by both return intervals and fire severity. Both warm moist and cool moist potential vegetation type groups contain the largest relative percentage of old growth forest cover types. These two potential vegetation type groups are also characterized as having a mixed severity fire regime. Such a mixed severity fire regime would give rise to a wide variety of forest cover types and structural stages. Old growth forest cover types would also be expected to be highly variable, exhibiting both homogeneous cover types dominated by a single species or limited species mix of either early or late successional species and heterogeneous species compositions containing a combination of both early seral and late successional species.

Table 51. Distribution of old growth forest cover types by broad potential vegetation type (PVT).

Broad PVT group	Estimated Old Growth Forest PVT Percent Cover	Confidence Interval Low (90%)	Confidence Interval High (90%)
Warm Dry	22%	15%	30%
Warm Moist	36%	28%	45%
Cool Moist	34%	26%	42%
Cold	7%	3%	12%

Includes ALL old growth habitat type/dominance type.
Source: R1 Summary Database, FIA Hybrid 2015 dataset.

Existing old growth on the Nez Perce-Clearwater occurs as several cover types (Figure 12). Grand fir is the most common old growth cover type followed by Douglas fir and Engelmann spruce or subalpine fir. Both grand fir and Douglas fir occur primarily within the warm moist potential vegetation type group, while Engelmann spruce or subalpine fir along with lodgepole pine occurs within the cool moist potential vegetation type group. Only a trace amount (0.04 percent) of Pacific yew (*Taxus brevifolia*) is estimated to occur on the forest. This old growth cover type is generally associated with grand fir and Western redcedar habitat types. The cover type noted as “None” reflects plots where the dominant species could not be classified.

Old growth forest cover types on the Nez Perce-Clearwater may exists across a range of broad potential vegetation type groups, as well as gradients between broad potential vegetation type groups. Table 52 illustrates the distribution of old growth cover types across broad potential vegetation type groups as a percentage of each dominant cover type. The table does not include potential combinations of species, which may make up the total species composition of a given old growth patch.

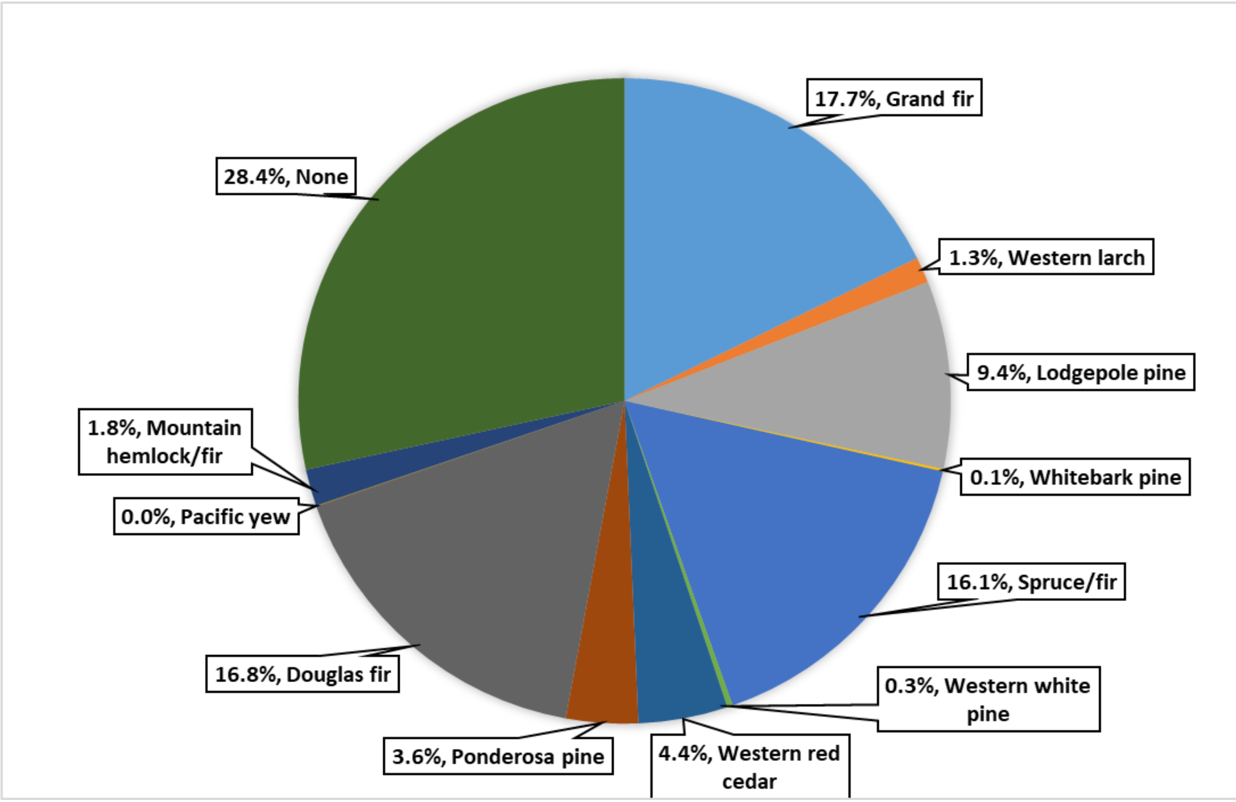

Figure 12. Cover type distribution of old growth.

Data Source: R1 Summary Database, FIA Hybrid 2015 dataset.

Table 52. Distribution of old growth cover types within broad potential vegetation types.

Old growth cover type	Warm Dry	Warm Moist	Cool Moist	Cold
Grand fir	34%	64%	2%	0%
Western larch	33%	50%	0%	17%
Whitebark pine	0%	0%	100%	0%
Lodgepole pine	23%	11%	30%	36%
Engelmann spruce or subalpine fir	2%	5%	67%	26%
Western white pine	0%	100%	0%	0%
Ponderosa pine	100%	0%	0%	0%
Douglas fir	42%	36%	20%	1%
Western redcedar	1%	99%	0%	0%
Pacific yew	0%	100%	0%	0%
Mountain hemlock or subalpine fir	0%	8%	54%	38%

Data Source: R1 Summary Database, FIA Hybrid 2015 dataset.

Each old growth habitat type may be expressed by several dominant old growth cover types. Cover types may occur as a single dominant species or more commonly as combinations of co-dominant species (Milburn et al. 2015) (Cooper et al. 1991). Table 53 illustrates the relationship between old growth habitat types and potential old growth cover types as a function of broad potential vegetation type. For old growth habitat type group “A,” 100 percent of all old growth cover types occur within the warm dry broad potential vegetation type. Within each old growth habitat group, the old growth cover type expressed at any point in stand development is largely the result of both succession and disturbance events. The nexus between climate regime and fire regime determines both the frequency and severity of disturbance events. A late seral old growth structure may develop into a near climax structure with a more tolerant species composition in the absence of disturbance. This same late seral old growth stand may maintain species composition following a disturbance, resulting in the maintenance of the late seral old growth structure.

Table 53. Relationship between old growth habitat type group and potential cover types.

Old Growth Habitat Type Group	Broad Potential Vegetation Type	Potential Old Growth Cover Types	Estimated Percent Cover Type Within Habitat Type Group
A	Warm Dry	PIPO, PSME	100%
B	Warm Dry	PIPO, PSME	97%
B	Warm Moist	PIPO, PSME, LAOC, PICO	1.7%
C	Warm Moist	PIPO, PSME, ABGR, LAOC, PICO, PIMO, TABR, PIEN/ABLA	100%

Data Source: R1 Summary Database 2015 Hybrid dataset

Possible management strategies to promote and maintain each old growth type are presented in Table 54. Opportunities for maintaining and promoting old growth types do not exist for all old growth types found on the Nez Perce-Clearwater. For example, an Old Growth Type 2 stand expressed as a lodgepole pine old growth cover type within the warm dry broad potential vegetation type is very unlikely to persist given the associated fire regime. Old Growth Type 4 may occur within several broad potential vegetation types and exhibit numerous old growth cover types. Such an Old Growth Type 4 stand could be managed to maintain late seral old growth structure which may improve stand resiliency from effects of wildfire.

Table 54. Old growth forest potential management strategies.

Old growth type	Old growth habitat type group	Potential management strategies
1	A, B	This old growth type has a minimum age of 150 years and, since it was maintained by frequent low severity fire, plan components seek to restore and maintain this old growth type in a late seral structure by using treatments that mimic this type of disturbance. Potential treatments may include prescribed burning to minimize the development of a shade tolerant understory which reduces stand resiliency.
2	B, C, D, E, G, H, I, J, K	Since fires historically occurred at frequencies of less than 100 years to 150 years, the maximum length of time this old growth type would have persisted would be 30 years. However, since that is the maximum length of time, it is unlikely that this would have been a historically abundant type of old growth and indicates that these forest types often did not historically meet old growth criteria. This old growth type will not be emphasized due to rare opportunities for management and the fire return frequencies needed to meet other resource objectives.
3	C, C1, G1	This type has a minimum age of 150 years old. It appears that this type occurred before the advent of effective fire suppression and, therefore, may have been important in small quantities. Plan components are designed to promote this rare old growth type through appropriate application of fire suppression where Pacific yew occurs.
4	C, C1, D, E F, G, G1, H, I	This type primarily occurs where Western white pine and Western larch were historically important cover types (Jain et al. 2004). The habitat types where Engelmann spruce (ES)/subalpine fir (SAF) would have occurred historically at greater than incidental amounts are within the cool moist potential vegetation type group as categorized by Milburn, Bollenbacher, Manning, and Bush (2015). The sites specified for Douglas fir, grand fir, Western larch, Western white pine, and Ponderosa pine old growth types are all within either the warm dry or warm moist potential vegetation type where Engelmann spruce/subalpine fir would have only occurred in incidental amounts. Since approximately 85 percent of the Engelmann spruce/subalpine fir potential vegetation type group occurs within Management Area 1 and Management Area 2, management for the purpose of maintaining the Engelmann spruce/subalpine fir old growth type is not emphasized within this group. Douglas fir and grand fir cover types are overrepresented on the forest and often do not reach sufficient age to meet old growth on the Nez Perce-Clearwater. Since these forest types are over-represented compared with historic conditions and often do not long persist as old growth, these old growth types are not specifically protected by Land Management Plan components. Western larch, Western white pine, western hemlock, and Ponderosa pine old growth types are all under-represented across all potential vegetation type groups and management areas. Plan components that maintain them as old growth will be emphasized to meet both old growth retention and dominance type objectives.

Old growth type	Old growth habitat type group	Potential management strategies
5	F, G, G1, H, I	Groups F and G are within the western redcedar (WRC) and western hemlock (WH) series habitat types. Engelmann spruce/subalpine fir and mountain hemlock/subalpine fir would have been historically unimportant within these habitat type groups. Stand dynamics indicate that even if these old growth types developed within a frost pocket on an otherwise WRC or WH site, they would not have long persisted as old growth because they would have been supplanted by WRC or WH. This is verified in Green et al. that on the wetter WRC habitat types, SAF and ES "develop rot early and seldom reach ages of more than 190 years." Thus, the most important occurrence of this type of old growth would be in the cool/moist potential vegetation type group, of which 85 percent is within roadless or wilderness areas. Maintenance and protection are emphasized for the WRC and WH habitat types.
6	I, J, K	Fire suppression has resulted in conversion of many stands to subalpine fir. This old growth type only occurs within the cool/moist and cold potential vegetation type groups. Plan components for this old growth type focus on restoration and maintenance where this type occurs due to severe underrepresentation of whitebark pine (WBP) on the landscape and the supplanting of WBP by subalpine fir.
7	F, G, G1	These types occur in areas protected from summer drought, which indicates that this type of old growth often occurs in riparian areas, areas with a very deep ash cap and typically wet summer precipitation pattern. Observations on the Clearwater National Forest suggest that historically this old growth type may have developed underneath an overstory of Western white pine. Plan components are intended to promote this old growth type.
8	J	This old growth type occurs almost exclusively in the cool/moist potential vegetation type group. Since WWP, WL, and DF are associated with warm moist potential vegetation type groups they are not a significant component of this old growth type. Plan components, which favor maintenance of Engelmann spruce/subalpine fir and mountain hemlock/subalpine fir old growth types, are emphasized.
9	K	This type is almost completely within the cold potential vegetation type group and this type gained in prevalence at the expense of the whitebark pine type. Plan components are designed to promote and maintain whitebark pine within this old growth type due to the prevalence of Engelmann spruce/subalpine fir and mountain hemlock/subalpine fir types and the declining whitebark pine component.

Over the last century, a combination of fire suppression and selective logging practices has promoted the development and retention of old growth forest cover types dominated by intolerant species. Intolerant species such as grand fir are highly susceptible to effects of wildfire and are the preferred host species for a wide variety of forest pests and plant diseases (U.S. Department of Agriculture 2014e). Climate change models are predicting a shift toward a warmer drier climatic regime for the western United States which may increase moisture stress within forested ecosystems (Millar and Stephenson 2015). Projected changes in climatic regime are predicted to influence the frequency, intensity, and duration of disturbance events at all scales (Dale et al. 2001, Marlon et al. 2012), which is projected to challenge the resiliency of forest ecosystems to stresses. The primary stressor effecting forest ecosystems of the Nez Perce-Clearwater will be wildland fire. The Land Management Plan focuses proposed management actions on forest cover types which are fire adapted to promote a species composition more resilient to changes in fire regimes (Hessburg et al. 2015).

The estimated distribution of dominance types across the Nez Perce-Clearwater is considerably outside of the natural range of variation for dominance types based on the natural range of variation analysis generated from the SIMPPLLE model (see Appendix B). Both grand fir and Douglas fir comprise approximately 35 percent of all old growth cover types on the forest based on current Forest Inventory and Analysis data. Given that the composition of grand fir and Douglas fir is outside of the modeled natural range of variation for these species, any proposed old growth management strategy should incorporate thinking about forested vegetation as a whole, rather than simply restricting activities within all old growth (Bollenbacher et al. 2014). To do this, plan components are designed to deal with our underrepresented dominance types while allowing vegetation management within overrepresented dominance types.

Old growth cannot be modeled because the definition requires information, which is only available in plot or stand-level field inventory; such data is not mapped across the Nez Perce-Clearwater, nor can it be derived with SIMPPLLE. Therefore, there is no means to determine a quantifiable estimate of the natural range of variation for old growth amount, patch size, or distribution. The historic condition must be inferred from other attributes. Tree size class can be reliably estimated using Forest Inventory and Analysis and R1 VMap. Because old growth definitions are based in part on the presence of large trees, a correlation can be drawn with the presence of large-tree structure. The definition of large-tree structure was developed using the minimum large tree criteria found in old growth definitions as a reference point (Green et al. 1992, Milburn et al. 2019). These areas are the most likely to contain sufficient large trees to be old growth.

Estimates of the natural range of variation derived from the North Idaho analysis area suggest a mean of about 22 percent (range 19–24%) of the landscape had large-tree structure. Refer to Appendix B for a discussion of the natural range of variation analysis for large-tree structure in the North Idaho analysis area. On the Nez Perce-Clearwater, large-tree (15–19.9” diameter at breast height [DBH]) structure is not as ecologically meaningful as very large tree (20 +” DBH) structure for most cover types. Exceptions occur within the cold potential vegetation type group including lodgepole pine, Engelman spruce or subalpine fir, or mountain hemlock or subalpine fir old growth cover types. These types rarely achieve diameters over 15” DBH. Much of the land area of the Nez Perce-Clearwater is highly productive and capable of growing trees 15–19.9” DBH within 80 years. These trees are much younger than the minimum screening criteria age for most old growth forest types.

The natural range of variation analysis area revealed very few areas meeting the selection criteria of very large trees only. This indicates that very large trees are highly correlated with the presence of large trees. The preponderance of the area meeting large-tree structure and classified as “both,” which indicates that the area meets both large-tree and vary large-tree criteria. The mean of this “Both” natural range of variation analysis estimate is 24 percent (range 21–27%). The estimated mean for large-tree structure meeting the large-tree only classification is 22 percent (range 19–24%). Not all areas would have been old growth because factors, such as tree age and density, are not reflected. It is important to recognize that not all old growth forest types can grow into the large-tree structure classification of “Both” due to site limitations and species characteristics. Species such as lodgepole pine and mountain hemlock or subalpine fir old growth types generally to not achieve diameters larger than 20 inches. To estimate a possible proportion, the current relationship between large-tree structure and old growth is explored.

About 20 percent (range 15–25 percent) of the Forest Inventory and Analysis plots that currently have a large-tree structure classification of large-tree only on the Nez Perce-Clearwater classify as old growth. Approximately 55 percent (range 49–61 percent) of Forest Inventory and Analysis plots are currently classified as having both large-tree and very large tree structure and classified as old growth. See Appendix B, Table 12, and Table 13 for an illustration of the calculations for the natural range of variation estimate of old growth forest cover types.

If this proportion were applied to the natural range of variation estimates of large-tree and both large-tree and very large tree structures, then it can be postulated that a natural range of old growth forestwide may have been 4–5 percent for old growth types meeting the large-tree only (15–19.9” DBH) class. These old growth types are generally associated with the cold and cool moist broad potential vegetation types and include lodgepole pine, mountain hemlock or subalpine fir, and Engelmann spruce or subalpine fir old growth types. The natural range of variation estimate for old growth types meeting the "Both" large-tree structure classification has a mean between 12 and 15 percent. Based on this, it is reasonable to conclude that the current level of old growth on the Nez Perce-Clearwater (11 percent) is likely within historical levels of old growth. This conclusion is supported by the finding that the existing abundance of large-tree structures and size classes are appropriate to maintain old growth structure on the forest. Roughly one-half of all old growth forest types occur within the warm dry and warm moist broad potential vegetation type groups. These old growth types are typically capable of growing into the very large diameter class and are associated with the large-tree structure classification of "Both" exhibiting both large and very large tree structures. By contrast, the other one-half of all old growth forest types are associated with the cool moist and cold broad potential vegetation type groups. Old growth forest types occurring within these types generally do not grow into the very large diameter class and are typically associated with the large-tree structure class of large-tree only.

Fire exclusion, particularly in low elevation warm dry sites, has altered vegetation structure and composition. Increasing tree densities, canopy layers, and shade tolerant species have increased tree stress and vulnerability to insects, disease, and wildfire. Old growth that may have existed on non-National Forest System lands has probably been removed over the past 100 to 120 years through harvest or conversion of lands to other uses, such as agriculture. Spatial arrangement and patch size are important characteristics of old growth. The average size of remaining old growth patches on all land ownerships are likely less than they were in the more recent past, particularly in areas where large patches were fragmented by disturbance and land development patterns.

All old growth components in the action alternatives are applicable only in Management Area 3 because neither Management Area 1 nor Management Area 2 are suitable for timber production. In public interactions regarding old growth, the chief concern with old growth appears to be the extent to which timber harvest would impact the amount of old growth on the national forest. Management Area 1 includes lands that are designated, such as wilderness, and where timber harvest is not expected to occur. Management Area 2 is comprised primarily of Idaho Roadless Areas, with much of the land inaccessible for timber harvest and where timber harvest is allowable as a tool to reach desired conditions, but timber harvest may not be used for the sole purpose of producing timber as a commodity. Because of this, management of old growth is not expected to cause measurable variation in old growth in Management Area 1 and Management Area 2 between the action alternatives and the no action alternatives. Thus, the following discussion is focused on how lands within Management Area 3 would be managed and the effect that management would have on old growth.

The 2012 Planning Rule (U.S. Department of Agriculture 2012c) states that "The plan must include plan components, including standards or guidelines, to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity, taking into account…System drivers, including dominant ecological processes, disturbance regimes, and stressors, such as natural succession, wildland fire, invasive species, and climate change; and the ability of terrestrial and aquatic ecosystems on the plan area to adapt to change. (v) Wildland fire and opportunities to restore fire adapted ecosystems."

Snags and Snag Retention

Plan components for Alternatives W, X, Y, and the Preferred Alternative require a specified number of snags per 100 acres with a diameter of 15 inches diameter at breast height (DBH) or larger. Plan components for Alternative Z require a specified number of snags per 100 acres that are 10 inches DBH and greater. Existing conditions for all snag species combined are described at the forestwide scale for each management area and broad potential vegetation type group in the following tables. Estimates for existing snags per acre are derived from Forest Inventory and Analysis data located in the Northern Region Summary Database.

Table 55. Forestwide desired condition and estimate of snags per acre by potential vegetation type (PVT) group and size class. DBH = diameter at breast height.

Dominance Group	PVT Group	≥ 10' DBH Desired Minimum[1]	≥ 10' DBH Existing Condition	≥ 15" DBH Desired Minimum	≥ 15" DBH Existing Condition	≥ 20" DBH Desired Minimum	≥ 20" DBH Existing Condition
Lodgepole pine	All	1	23	1	5	1	1
All Other Species	Warm Dry	1	15	2	5	1	2

Desired conditions for snags are based on the publication Estimates of Snag Densities for Northern Idaho Forests in the Northern Region (Bollenbacher et al. 2009b). Forest Inventory and Analysis plot data analyzed at the management area scale reveal that all management areas and broad potential vegetation type groups currently meet the desired conditions for the minimum number of snags per acre except the cold potential vegetation type group in Management Area 3. This is likely due to the combination of species compositions, such as lodgepole pine and subalpine fir which rarely grow to the 20-inch diameter at breast height size, and slow growth rates associated with the cold potential vegetation type group.

Non forested vegetation

The desired condition is to maintain or increase the extent of non-forested plant communities, primarily grass, and riparian grasses or shrubs. Non-forested cover types will be promoted with future warm and dry climate. Although modeling is limited for these types, the subsequent section provides more description of the existing and desired conditions for non-forested potential vegetation groups, cover types, and specific species. It is desirable to limit the encroachment of coniferous tree species onto non-forested potential vegetation types.

Climate change

It is the conclusion of the authors of the Northern Rockies Adaptation Partnership climate change assessment (Keane et al. 2018), that "assessing vegetation change and vulnerabilities is currently more of an educated guess based on inconsistent and contradictory studies rather than a highly confident evaluation of comprehensive scientific investigation." Therefore, taking a relatively broad approach to management of the Nez Perce-Clearwater is prudent, focusing on strategies that increase the resilience of vegetation to allow adaptation to whatever changes the future may bring.

Climate is integrated into the SIMPPLLE model and a major driver of vegetation change and effects of the alternatives over time. There is a great deal of uncertainty surrounding climate change and its potential effect on vegetation conditions. However, best available science was used to guide both the integration of future climate conditions into the SIMPPLLE model, and the evaluation of the vegetation change related to direct and indirect effects of climate change. Whether it is invasive species (for example, white pine blister rust), drought, uncharacteristic wildfires, elevated native insects and disease levels, unusually high forest densities, or some other agent or combination of agents that serves to stress trees and forest ecosystems, recent research suggests that climate change will likely exacerbate those stressors and "stress complexes" will continue to manifest themselves (Halofsky, Peterson, et al. 2018a, b).

Environmental Consequences

Effects Common to All Alternatives

Warm and dry climate, vegetative succession, wildfire, and insect and disease activity would be the primary shapers of vegetation under all alternatives. While planned treatments could vary by alternative and alter the probability or effects of some drivers, these processes will remain dominant. Recent studies have indicated that climate and drought, coupled with natural disturbances, have the potential to impact ecosystems much more than human interventions but that management within that context may be important to reduce the potential for forest decline or ease transitions into new, more resilient states (Cohen et al. 2016, Millar and Stephenson 2015, Golladay et al. 2016, Halofsky, Peterson, et al. 2018a, b).

Under all alternatives, vegetation characteristics will influence, and be influenced by, spatial heterogeneity of landscapes and interrelated drivers such as wildfire, climate, and insects. Fire suppression will continue to alter successional processes, although vegetation treatments may mitigate this influence somewhat. Fire exclusion would favor shade-tolerant species, small to medium size classes, and denser forests. Conversely, large fires will influence vegetation in a variety of ways such as reducing density, returning sites to an early successional stage, promoting large tree growth, or favoring fire tolerant species depending on the severity of fire. Warmer, drier climates will influence species distributions and successional processes in complex and uncertain ways. For example, species better adapted to warm, dry conditions such as Ponderosa pine may gain a competitive advantage. Drought may inhibit tree growth in some areas.

There has been a general trend of decreasing patch size and increased landscape fragmentation compared to the historic condition within the Nez Perce-Clearwater plan area. Spatial heterogeneity will play particularly important roles for the production of wildlife habitat, with thresholds in habitat quality, habitat connectivity, or patch size apparent for many species (Turner et al. 2013).

The terrestrial vegetation indicators modeled into the future vary by alternative; however, this variance is very subtle at the broad scale. This is because all alternatives were modeled and projected with a similar climate regime and similar levels of natural disturbance. Natural disturbance regimes are the primary influences on vegetation across the vast majority of the Nez Perce-Clearwater, due to the extent of areas where little active management occurs (such as wilderness, recommended wilderness, inventoried roadless areas, primitive recreation settings, and the like). Vegetation management actions such as timber harvest projected by the PRISM model were applied in the SIMPPLLE model. While these treatments undoubtedly result in modified vegetation characteristics where they occur, the overall level of treatment is not substantially different across alternatives and the impacts of treatments are generally outweighed by other influences when the key indicators are summarized at the broad scale.

The following sections display expected trends for terrestrial vegetation indicators for the 50-year modeling period. Thirty simulations are run to capture a range of variation around the estimated conditions. Tables and figures in the following sections indicate the mean estimate of each condition depicted across 30 model runs, along with the existing condition and desired condition ranges. In some cases, the existing condition (based on Forest Inventory and Analysis plots) is not consistent with the starting condition of SIMPPLLE (based on R1-VMap), due to the disparity in data sources as described in Appendix B. The expected trend is more crucial to the analysis than the overall endpoint. See Appendix B for additional charts and modeling results.

Non-forested vegetation, forest savannas, and xeric ecotones

At the forestwide scale, non-forested cover type acres are predicted to increase from decades 1 to 3 and then slightly decrease but remain above the existing condition. The starting condition for SIMPPLLE is below the actual condition estimated with Forest Inventory and Analysis plots, and the expected trend would likely result in conditions within but trending toward the lower bound of the desired range for most future decades at the forestwide scale, as well as in in the warm dry and cold broad potential vegetation types. Conditions would be at the mid to upper end of the desired range in the warm moist and cool moist broad potential vegetation types.

Non-forested cover types are not expected to decrease in any management area. Potential decreases in non-forest cover types may occur as both a result of desirable reforestation of disturbed areas, as well as the loss of historic grass communities to conifer encroachment. In no management area does the model predict that the abundance of non-forested cover types increases substantially.

At the forestwide broad scale, the expected effects of future warm dry climate and drought include the maintenance or expansion of non-forested communities (particularly xeric types) as sites become too dry or frequently disturbed to support forest cover. At the local scale, modeling indicates that such a trend would not be substantially realized in the next 50 years, although the results are complicated by our inability to tease apart the relationship between the reforestation of disturbed forested sites, versus the expansion or loss of true non-forested plant communities. Further, other factors such as fire suppression play a role.

Xeric ecotones are among the most sensitive ecosystems to climate change (Tomback et al. 2011). Lower treeline woodlands are often thought to be “invading” desirable grass types due to fire suppression and grazing; however, ecotones also naturally move along elevational gradients based on the dynamics of vegetation, climate, and fire (Tomback et al. 2011). Drivers of this trend are primarily fire exclusion which would have killed encroaching trees when they were of a small size, possibly exacerbated by grazing which reduced fine fuel loads and further influenced fire exclusion. Threats to the xeric ecotone include loss of tree species to disease, insects, and fire as well as shifts in warming and drying patterns because of climate change.

Vegetation Composition

Vegetation composition is expected to change through time as depicted in the following sections for dominance types within broad potential vegetation type groups and non-forested cover types. Appendix B contains tables and figures showing the model results. For all broad potential vegetation type groups, the expected trends are similar across all alternatives and negligible when viewed at the forestwide scale.

The expected trend of some dominance types would move towards the desired condition, including increases in tree species presence and cover types associated with Ponderosa pine, Western white pine, and Western larch and decreases in tree species' presence and cover types associated with grand fir. Conversely, other results indicate a trend away from the desired condition, including a static condition in the extent and dominance of western redcedar and increases in lodgepole pine. Several key species, including aspen and whitebark pine, are projected to increase above current levels. The forestwide trends and conclusions do not apply equally to every broad potential vegetation type or every management area.

Indirect effects common across all Management Areas

Forest Density

Forest density class and vertical structure is expected to change through time as depicted in the following sections and figures. Appendix B contains charts of model outputs. For all types, the expected trends are similar across all alternatives and negligible when viewed at the forestwide scale.

At the forestwide scale, the expected trend of density class distribution would generally move towards the natural range of variation, including increases in the low to medium class and decreases in the high class in response to increased frequency of disturbance at landscape scales. The trends are expected to be positive relative to forest resilience because, in general, the denser the forest the greater the likelihood that fuel characteristics could support a fast-moving intense crown fire due to greater fuel quantities and the vertical and horizontal continuity of fuels. Lower forest densities are desired near communities or other values at risk to fire. In addition, as the density increases, a deficit of soil moisture may develop and trees lose their ability to withstand attacks by insects, pathogens, and parasites (Safranyik et al. 1974). Lower densities also support enhanced individual tree growth, and therefore the expected shifts likely contribute to the increases in the large tree size classes and concentrations described above. The forestwide trends and conclusions do not apply to every potential vegetation type or every management area; these variances are described in the sections below and in Appendix B.

For the purposes of density class, areas are considered non-forested or do not have a density class assigned when there is less than 10 percent canopy cover of trees present. Such areas are considered in the early seral stage of development. This early seral stage may persist from one to several decades in Management Areas 1 and 2 in the absence of artificial regeneration practices. There is overlap in the occurrence of forest savannas in areas considered non-forested for density class. Only forested density classes are discussed in this section.

Low to Medium Density: Forestwide, the SIMPPLLE model projects that the low to medium density class (10–39.9% canopy cover) would decrease over the first two decades and begin to trend upward by the end of the projection period (5 decades). This trend is consistent with all alternatives and is on the lower bound of the desired condition range. The decrease in this condition may be due to natural disturbances, which increase the percent of area in the early seral stage. Forest succession moves these areas from early seral stage into areas of dense regeneration. In some cases, these areas may also encompass sites that were previously non-forested where forest cover has become established.

The trend for all broad potential vegetation types is a decrease in the number of acres exhibiting the low to medium density class, with the most dramatic decrease occurring in the warm dry potential vegetation type group. The decrease is more subtle in the warm and cool moist broad potential vegetation types as the forests found there tend to naturally grow at higher densities (such as grand fir and lodgepole pine), and in fact may exceed the desired condition range for one to several decades until natural disturbance events reduce densities.

Medium to High Density: Forestwide, the medium to high-density class (40%+ canopy cover) increases over time. The starting condition for SIMPPLLE is particularly far removed from the actual existing condition measured on Forest Inventory and Analysis plots. However, the trend of increase would indicate that this class moves above the desired range by the end of the modeling period. The increase in the high-density class likely corresponds to the decrease in the low to medium class across all broad potential vegetation types.

This class increases on cool moist types, which over time achieves the desired range; most forest types on these sites would naturally grow in this density condition at least in the later stages of stand development. This condition fluctuates on the cold broad potential vegetation type, remaining within the desired range.

All broad potential vegetation types include similar increases of this density class, along with existing conditions that are not well-represented by the SIMPPLLE starting condition. The trends in the warm dry and cool moist types would achieve and possibly move above the desired ranges by the end of the modeling period, whereas the increase would still be trending toward desired conditions in the cold type. Drought conditions and expected future disturbances are likely the main drivers for future reductions in the medium to high density class. The reductions of the high-density class could result in higher forest resiliency to disturbances in many cases, and result in promoting large trees and shade-intolerant species. Conversely, in some cases shifts to lower densities could equate to the loss of habitats of interest (such as dense spruce and fir for lynx habitat).

Landscape resiliency

The following indicators of key ecosystem characteristics for landscape resiliency each effect and are affected by application of each alternative. Taken together, vegetation pattern, vegetation condition class, and insect and disease hazard rating are indicators of departure from desired conditions.

Vegetation Pattern

The size of early successional forest openings is expected to change over time. The effects analysis was conducted allowing patches to be considered openings for as long as they remained in the seedling or sapling size class condition. Rates of forest succession vary between broad potential vegetation types as well as between habitat types within each group. Patches may persist in the seedling or sapling stage from one to several decades. The two indicators used are the average patch size, which is a simple arithmetic mean and the area weighted mean, as defined in the affected environment section. Appendix B contains charts forestwide and for each broad potential vegetation type for each alternative, compared to the desired ranges. The expected trends are similar across all alternatives and negligible when viewed at the forestwide scale; therefore, the outputs for the alternatives are averaged in the figures below.

Figure 13 provides the trend over 5 decades of average patch size and Figure 14 shows area weighted mean patch size. The natural range of variation for patch size is illustrated for comparison of trends. Forestwide, the average size of early successional forest patches is projected to increase through decade 5. This trend moves into the bottom quartile of the natural range of variation and remains within the natural range of variation through decade 5. The average patch size increases for Management Area 1 at a faster rate than for the other management areas but remains below the forestwide average.

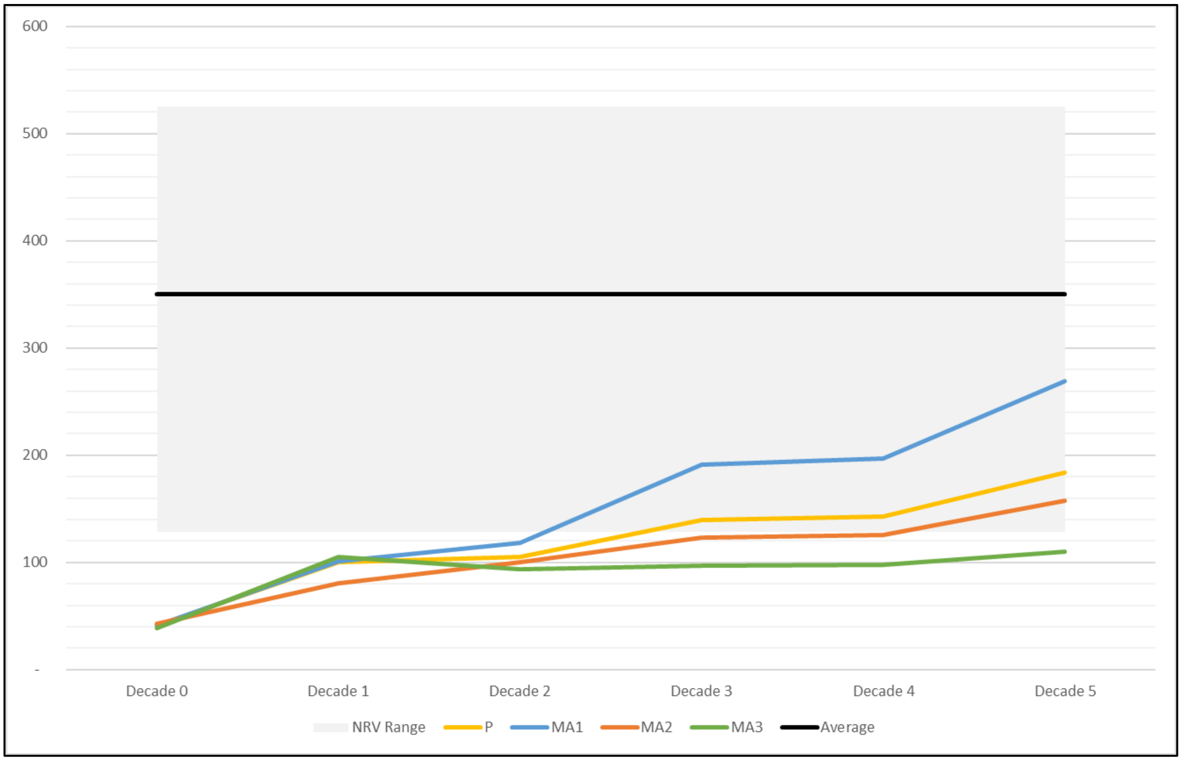

Figure 13. Average early successional forest patch size (in acres, average of alternatives) by decade.

NRV=Natural range of variation. P=Preferred Alternative. MA=Management Area. Average=Forest-wide average.
Data Source: SIMPPLLE model.

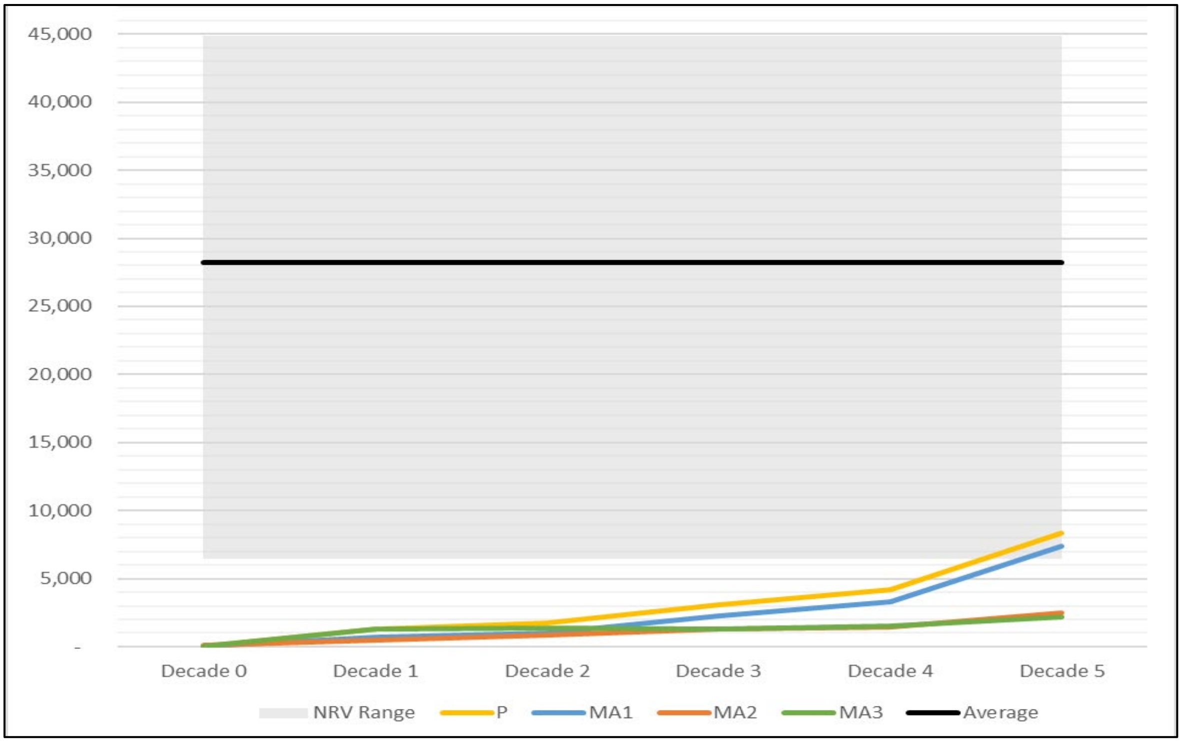

Figure 14. Area weighted mean for early successional forest patch size (in acres, average of alternatives) by decade.

NRV=Natural range of variation. P=Preferred Alternative. MA=Management Area. Average=Forest-wide average.
Data Source: SIMPPLLE model.

The area weighted mean patch size generally increases forestwide through decade 5 and for all management areas. The forestwide trend increases rapidly after decade 2 and approaches the bottom quartile of the natural range of variation by decade 5. Area weighted mean patch size increases for all management areas. The trend line for Management Area 1 increases at a faster rate than trends for Management Areas 2 and 3 but remains below the natural range of variation average. Area weighted mean patch size increases for Management Areas 2 and 3 but generally remains below the natural range of variation range. Trends are similar for all management areas but differ in magnitude from Management Area 1. The trend for the Preferred Alternative is like the trend for Management Area 1.

In the short term, the increase in area weighted mean patch size is the result of the combined effects of increased vegetation management, forest restoration, and wildfire events. The magnitude of predicted change within Management Area 3 reflects continued fire suppression within the roaded front. Increases in the predicted size of large fires are reflected by the trend line for Management Area 1.

Increases in the harvest schedules associated with the action alternatives indicate a slower increase in the trend toward the natural range of variation average for Management Area 3. The existing condition falls at the low end of natural range of variation for all management areas. Through the fifth decade, projections of area weighted mean patch size generally remain below the natural range of variation for all management areas.

Fire would continue to be the primary event that creates early successional forest openings, particularly the large sized openings. The pattern of openings intermixed with mid and late successional forest would be ever-changing over time and space. The primary cause of increasing patch size of early successional forests is likely the result of changing climate and land allocation decisions. Timber harvest and prescribed burning also create early successional forest patches, but at the forestwide scale the extent of these activities would be minor and not likely to affect mean patch sizes to a large degree. The increase in patch size is likely due to a history of fire suppression within the fire regimes typified by the potential vegetation type groups. A large proportion of the forested acres have missed several fire return intervals and are becoming increasingly susceptible to high severity fire affects.

The estimated patch sizes through time trends toward the natural range of variation for all broad potential vegetation types. Conversely, the patch size increases estimated across all broad potential vegetation types approaches the lower bound of the natural range of variation for Management Area 1. Seral species dominated forests, which are desirable forestwide, are adapted to reforesting large openings following disturbances; a coarser grained mosaic of patch sizes could provide for the maintenance of shade intolerant species such as Western white pine and Western larch in suitable areas.

Please refer to the Effects that Vary by Alternative section, Effects from plan components associated with timber management, for further discussion on Land Management Plan components that could influence the patch size of early successional forests.

Insect and Disease

Insect and disease hazard ratings and occurrence are expected to change over time in response to shifts in species composition, stand density, and size class distributions. The effects analysis performed with the SIMPPLLE model estimates a hazard rating for each insect and disease vector of interest based on species composition and size class over time. Changes in species composition, stand density, and size class due to management activities as well as natural disturbance events are modeled under a warmer and drier climatic regime and include other abiotic considerations such as elevation and slope position.

Effects of proposed forest management activities and natural disturbance events are consistent between alternatives. There is no defined desirable range for insect and disease occurrence at the forestwide scale. Figure 15 illustrates the expected trends in insect and disease occurrence over the 5-decade comparative period.

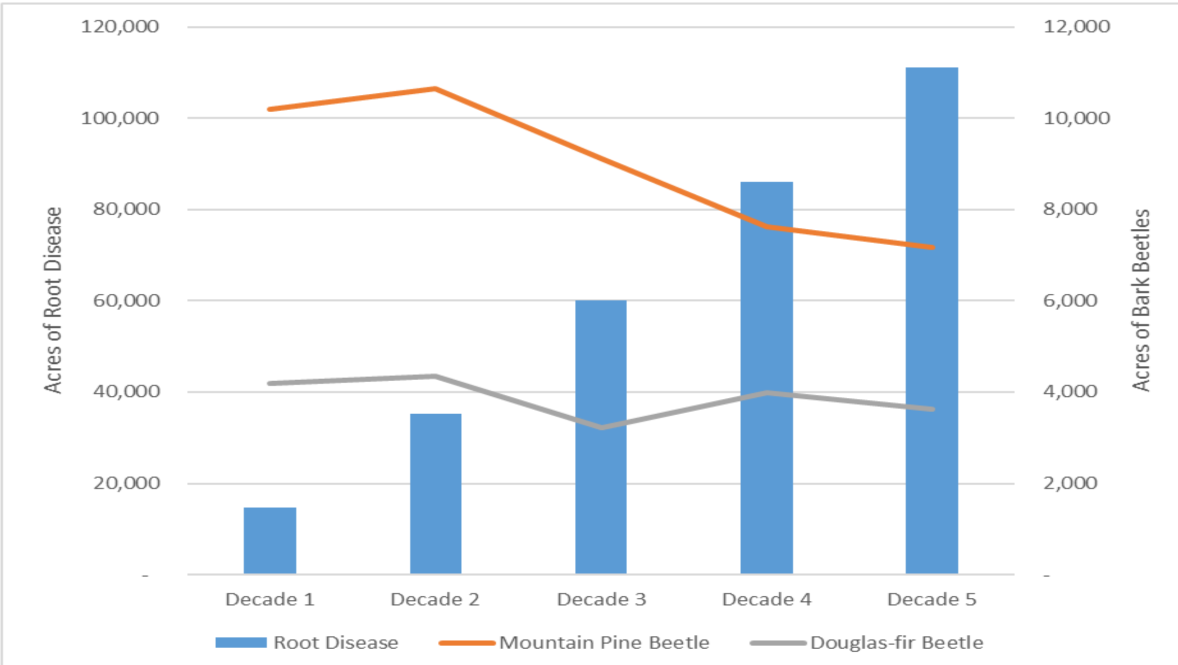

Figure 15. Insect and disease occurrence forestwide (average of alternatives) in acres of root disease (left axis, bars) and acres of bark beetles (right axis, lines).

Data Source: SIMPPLLE model

At the forestwide scale, root disease increases in each decade across all alternatives and broad potential vegetation type groups. The increase in root disease is correlated with the continued dominance of host species (Douglas fir and grand fir) as well as the continued expansion of existing root disease centers. As grand fir and Douglas fir composition rebounds following disturbances, so does the occurrence of root disease. Wildland fire would be expected to maintain levels of root disease at the decade 5 level.

Mountain pine beetle occurrence is a combination of host specific beetles effecting lodgepole pine, ponderosa pine, and whitebark pine. Beetle attacks are highly correlated with stand density and size class. In the short term through decade 3, there is a reduction in both lodgepole pine stand densities and size class which reduces the occurrence of mountain pine beetle. As lodgepole pine stands increase in size through decade 5, mountain pine beetle occurrence increases until disturbance once again reduces stand densities. Ponderosa pine follows a similar pattern and again is closely tied to stand density. Whitebark pine populations are increasingly affected by mountain pine beetle because of climate change effects and expanding whitebark pine populations.

Douglas fir beetle follows a pattern of decline over the 5-decade projection period. There is a significant reduction in Douglas fir beetle in the short term through decade 4, followed by a static trend through decades 4 and 5. The reduction in Douglas fir beetle is influenced by reductions in host species composition, stand densities, and size class.

Projected Wildfire

Wildfire frequency and severity is expected to shift toward the natural range of variation associated with each fire regime. This shift will influence ecosystem processes on the forest. A shift towards warmer-drier climatic cycle will produce conditions conducive to fire starts and wildfire spread which will influence species composition, stand densities, and size class distributions.

Trends for projected wildfire are consistent across all alternatives. At the forestwide scale, the percentage of seral species composition including Western white pine, Western larch, Ponderosa pine, and whitebark pine are increasing. Increases in seral species abundance are due to both improved conditions for establishment of seral species following fire disturbance and the Land Management Plan objectives of increasing the planting of seral species following wildland fire. Seral species composition, including aspen, is expected to increase approximately 10–20 percent over current levels in the 20-year short term comparative period and between 30 and 40 percent over the 50-year long-term comparative period. Western white pine is projected to increase from 4 percent to 8 percent of total species composition. Grand fir is projected to decline by 40–50 percent for the same 50-year comparative period.

Canopy structure is expected to shift toward more closed canopies (Figure 16). This trend is largely due to increases in early seral conditions which often composed of high seedling densities. These young forest stands develop into closed canopy stand until natural succession processes and disturbances begin to thin the canopy. At the forestwide scale, closed canopy conditions are projected to decrease slightly from an average of 54 percent to an average of 43 percent. During the same projection period, open canopy structures are modeled to trend from 42 percent downward to 29 percent. Early seral canopy openings are projected to increase from 4 percent to 28 percent. These changes in seral species composition and canopy structure are predicted to trend vegetation toward more resilient conditions functioning within the fire regimes of the forest.

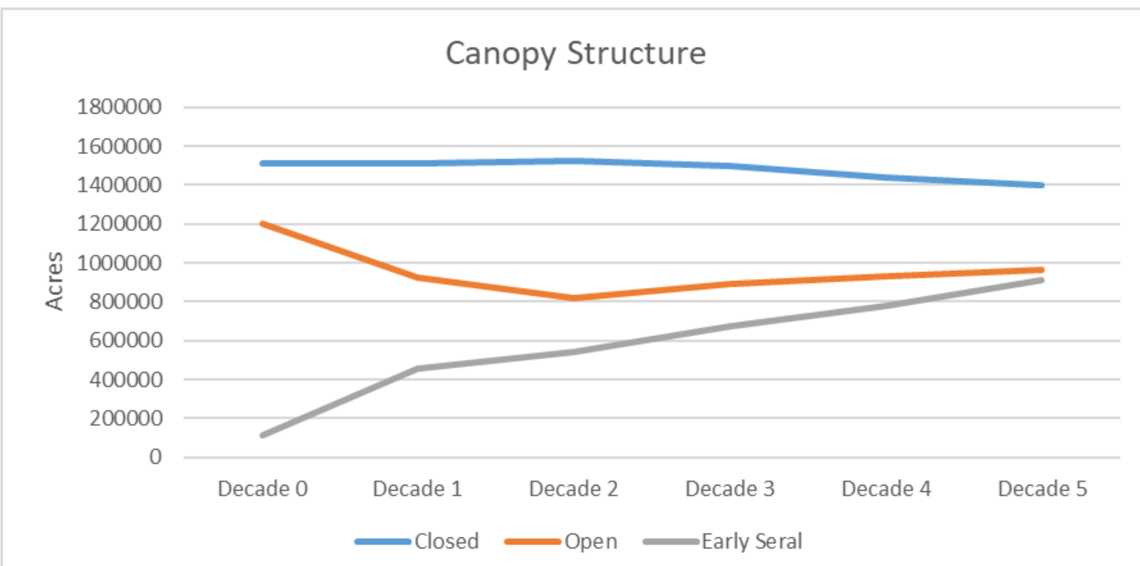

Figure 16. Forestwide canopy structure.

Data Source: SIMPPLLE model

Rare/Unique Habitat Elements

Under the No Action Alternative, the presence of aspen is not likely to change from the existing conditions. Existing disturbance agents and patterns may promote aspen regeneration in areas already occupied by aspen. Forest succession and lack of disturbance will likely continue to promote dominance of climax conifer species. Analysis of data derived from the SIMPPLLE model do not indicate an increase in either distribution or abundance of aspen. The primary driver for increases in aspen presence is stand replacing wildland fire within the cool moist and warm moist potential vegetation type groups.

Old Growth

The 1987 Clearwater Forest Plan specifies maintaining 10 percent of the national forest in old growth habitat, with 5 percent of each old growth analysis unit maintained as old growth. Additionally, former Forest Supervisor, Tom Reilly, issued direction prohibiting regeneration harvest in old growth and forest stands within 20 years of meeting old growth criteria until the national forest met its old growth goals.

The expectation at that time was that by following this strategy, the Clearwater Forest would achieve the 10 percent criteria and exceed it by the year 2012 as forest succession occurred. The Northern Region Summary Database 2015 Hybrid dataset indicates that the national forest has met the old growth standard at the 90 percent confidence level.

The report that showed that the Clearwater Forest did not meet the 10 percent criteria was taken from data collected between 1998 and 2002 (Bush et al. 2007). Bush et al. (2007) showed that with a 90 percent confidence interval, the estimated amount of old growth on the Clearwater Forest was 9.4 percent, the lower bound was 7.3 percent, and the upper bound was 11.8 percent. In this same report, they also state that all acres effected by harvest and fire that occurred between their estimates and the time the report was authored were considered to not meet old growth criteria.

The most current data available for analysis is referred to as the Hybrid 15 dataset and the Forest Inventory and Analysis data used for this dataset was collected between 2011 and 2017 (Bush et al. 2006). From the Hybrid 15 dataset, old growth estimates for the Nez Perce-Clearwater are calculated with a 90 percent confidence interval. Plots which experienced wildfire between 2015 and 2017 were re-measured and updated in the database. The current estimate of old growth forest structure is 10.55 percent, with a lower bound of 9.03 percent and an upper bound of 12.11 percent.

A best-case analysis indicates that the current strategy has kept old growth amounts near current levels and has done little to increase old growth. A worst-case analysis indicates that the amount of old growth on the Nez Perce-Clearwater may significantly decrease with an anticipated increase in stand replacing fire events. Since levels have remained about static with the current policy in place, it is reasonable to conclude that this policy of management has not had the desired effect and there may be some other reason why the amount of old growth has not increased as intended.

Forest Inventory and Analysis data show that about 84 percent of the Nez Perce-Clearwater is dominated by grand fir and Douglas fir, which are two of the tree species most susceptible to the most damaging root diseases on the national forests. Root disease modeling indicates that 17.3 percent of the Clearwater National Forest and 11.8 percent of the Nez Perce National Forest have moderate to high severity root disease (Lockman and Kearns 2016). This same report indicates a 25.8 percent and 25.5 percent of low severity root disease for the Clearwater National Forest and Nez Perce National Forest, respectively. When left untreated, root disease patches often develop into long-term brushfields (Hagle 2004).

Current management of old growth on the Nez Perce-Clearwater has been to avoid actions that would modify stands classified as old growth. According to Green et al. (2011), “Many of the oldest stands of old growth are dominated by seral tree species that are maintained as dominants and protected from crown fire by repeated underburns that reduce ladder fuels and competition from more tolerant tree species…the bulk of presettlement upland old growth in the northern Rockies was in the lower elevation, ground-fire maintained Ponderosa pine/Western larch/Douglas fir types." If the No Action Alternative is selected, it is likely that stands classified as old growth would not be managed to maintain them.

If the No Action Alternative is selected, short-term amounts of old growth are likely to stay constant as evidenced by the modest increase between numbers from 2006 and present. Longer term, given the prevalence of root disease-caused mortality and the lack of disturbance in stands where disturbance is necessary for maintenance, it is likely that the amount of old growth on the Nez Perce-Clearwater will decrease. As described above, root disease is expected to cause mortality in stands dominated by Douglas fir and grand fir, and these stands are not expected to persist as old growth. Additionally, the absence of disturbance favors these species, and they will eventually dominate old growth sites and supplant long-lived early seral species. In this way, a lack of management of old growth stands could cause the amount of old growth on the Nez Perce-Clearwater to remain at the same level as current or decrease.

As evidenced in the introduction to this section, the 2012 Planning Rule places a strong emphasis on natural range of variation, natural patterns and process, and integration among resources, rather than promoting a paradigm of preserving systems in a static condition. The direction from the existing Forest Plans focuses on preservation of an existing condition of old growth and does not deal with the need for restoring the ecology of the systems.

Action Alternatives – Indirect Effects

The action alternatives contain one standard (MA3-STD-FOR-01), two desired conditions (MA2-DC-FOR-10, MA3-DC-FOR-10), and eight guidelines (MA2 & MA3-GDL-FOR-01, MA2 & MA3-GDL-FOR-02, MA2 & MA3-GDL-FOR-03, and MA2 & MA3-GDL-FOR-04) that relate to old growth management. These plan components support desired conditions expressed in MA2 and MA3-DC-FOR-10 to support retention of resilient old growth cover types across all broad potential vegetation types.

If any of the action alternatives are selected, the combination of standard MA3-STD-FOR-01 and associated desired conditions guidelines would be expected to maintain the abundance of Ponderosa pine, Western larch, Western white pine, Pacific yew, Western redcedar, Western hemlock, and whitebark pine old growth cover types. These standard and associated guidelines would permit management of these old growth cover types consistent with historic disturbance processes that maintained these old growth cover types. For instance, some old growth cover types were maintained by low severity fire and were protected from stand replacing disturbance by these low severity disturbances (Green et al. 2011). These components would be expected to encourage disturbance that maintains these old growth cover types, and as a result, the amounts of the listed old growth cover types would be maintained.

Old Growth Conclusions

The action alternatives are consistent with the 2012 Planning Rule emphasis on restoration of pattern and process in that they promote disturbance for maintenance of old growth as well as promoting restoration of the more resilient old growth cover types that were historically prevalent.

The No Action Alternative seeks preservation of the existing old growth stands, but analysis shows that preservation may be infeasible, even with complete protection. The No Action Alternative seeks to exclude disturbance from old growth, whereas the action alternatives seek to use disturbance in a manner consistent with principles of disturbance ecology.

The action alternatives promote creation of resilient old growth by emphasizing creation of the types of old growth that were ecologically sustainable, longest-lived, and most prevalent (MA3-STD-FOR-01, MA3-GDL-FOR-01).

For the reasons listed above, the action alternatives best meet the 2012 Planning Rule and are most likely to result in resilient old growth.

Effects that Differ by Alternative

Dominance types

The following section describes dominance types resulting from modeled silviculture treatments and natural disturbances for each alternative. Modelling results are displayed for each management area and potential vegetation type group. The extent to which desired conditions for dominance type is achieved is a measure of the desirability of the alternative for vegetation management.

Dominance type is an important indicator of forest structure, forest resiliency, and disturbance regime. Dominance type influences the ability to use prescribed fire as well as wildfire effects. Snag and downed woody debris recruitment are affected by dominance type. Snags resulting from seral species tend to remain standing for longer periods than snags resulting from climax species. Long-term sustainability of forested ecosystems requires a species mix which is resilient to disturbance.

The following tables illustrate the extent to which forest vegetation trends toward desired dominance types in each alternative. The tables are projections of 20-year short term and 50-year long term comparative periods specific to each alternative from the present and show the effect each alternative has on dominance type by management area. Percent species compositions do not all sum to 100 percent due to exclusion of minor species components and non-forested acres, as well as differences in acres suitable for timber production specific to each alternative.

Table 57. The 20-year and 50-year projections for Cold potential vegetation type dominance types within Management Area 1 by alternative.

Dominance Type	LP	AF/ES	WBP	DF/WL	MH	Seral Stage grass/shrub
Desired Range %	30–40%	3–10%	35–50%	0–5%	2–5%	5–15%
No Action % 20 Yr. Projection	6	40	5	3	2	44
No Action % 50 Yr. Projection	27	41	8	9	2	19
Alt W % 20 Yr. Projection	6	40	5	3	2	44
Alt W % 50 Yr. Projection	27	41	8	9	2	19
Alt X % 20 Yr. Projection	7	40	5	2	2	44
Alt X % 50 Yr. Projection	27	41	8	9	2	19
Alt Y % 20 Yr. Projection	6	40	5	3	2	44
Alt Y % 50 Yr. Projection	27	41	8	9	2	19
Alt Z % 20 Yr. Projection	7	40	5	2	2	44

Comparison of effects across alternatives for Management Area 1 indicates similar results. Given that changes in vegetation composition derive only from natural disturbance events, the rate of change as indicated by each alternative is slow. Within the cold potential vegetation type groups, the subalpine fir and Engelmann spruce dominance type continues to dominate species composition beyond the desirable range. Increases in the grass or shrub seral stage in the short term are the result of wildland fire events. These disturbed areas are dominated by subalpine fir and Engelmann spruce dominance types in the long term. This is in part due to a lack of whitebark pine seed sources. This suggests that the modeled natural disturbance levels are sufficient to restore this high elevation ecosystem, but declines in whitebark pine populations continue to promote spruce and fir dominance types. Within the cool moist potential vegetation type modest gains are made in whitebark pine, Western larch, and Western white pine composition which reduces the percentage of subalpine fir and Engelmann spruce dominance type. Within the warm dry and warm moist potential vegetation type groups, the grand fir components decline toward the desired range and only modest gains in seral species composition is indicated. Douglas fir continues to dominate species composition in part due to available seed sources. As with the higher elevation vegetation types, this suggest a sufficient disturbance level to restore the warm dry and warm moist potential vegetation type groups to the desired ranges for species composition, but seral seed sources are lacking to promote Western white pine, Western larch, and Ponderosa pine dominance.

Management Area 2 is managed under the protocols identified in the Idaho Roadless Rule. Active management of these lands is limited in both scope and scale. Only 1 percent of these lands are subject to mechanical vegetation management per year. Wildland fire is the primary management tool used to achieve desired conditions. The effects of the limited vegetation management approach are illustrated in the following tables.

Consistent trends are evident when comparing effects across alternatives for Management Area 2. Management actions for moving vegetation composition toward desired conditions is limited to silvicultural treatments on lands suitable for timber harvest and wildland fire. It is expected that natural wildfire ignitions will be managed to promote ecological functions and limit negative effects to resource values of concern. Only 1 percent of the Idaho Roadless Rule area is subject to active forest management per year and prescribed burning is limited by budgets, physical capability, and airshed constraints.

Within the cold potential vegetation type group, lodgepole pine, and subalpine fir and Engelmann spruce composition increase slightly, while modest gains are made in whitebark pine and Douglas fir and Western larch dominance types. Response to disturbance produces similar results within the cool moist broad potential vegetation type group, lodgepole pine, and subalpine fir and Engelmann spruce remain static and modest gains are realized in seral species composition. Both trends, which are similar for all alternatives, are inconsistent with desired species composition. Modest gains are achieved to promote whitebark pine composition across all alternatives. No alternative performs to substantially increase either Western larch or Western white pine. This is in part due to a lack of available seed sources and the slow progress of artificial regeneration.

Within the warm dry broad potential vegetation type groups, Ponderosa pine species composition trends toward the desired range and Douglas fir increases above the desired range across all alternatives. Grand fir is reduced to within desired ranges within the warm dry potential vegetation type group across all alternatives. Disturbance levels within the warm moist broad potential vegetation type are sufficient to trend seral species toward desired ranges but generally remain outside of desired ranges. Tolerant species composition remains static.

The potential consequences of limited management and reliance on natural disturbance processes in Management Area 2 promote slower progress toward seral species dominance and retention of tolerant species. Shade tolerant species promote potential increases in acres affected by insect and disease, an increase in severe fire effects under a warmer and drier climate regime, subsequent negative impacts to soils and water resources and recreational esthetics, as well as loss of certain wildlife habitats. Snag densities are expected to substantially increase.

All alternatives maintain or trend most dominance types toward desired conditions for Management Area 3, as shown in the following tables. No alternative achieves target desired conditions for Western larch, Western white pine, Ponderosa pine, or whitebark pine. The distinguishing difference between alternatives is the number of acres treated. Within the cold potential vegetation type group, modest gains are achieved through reduction of subalpine fir and Engelmann spruce composition and trending toward desired conditions for lodgepole pine composition. The cool moist broad potential vegetation type group exhibits similar results for lodgepole pine, but subalpine fir and Engelmann spruce composition increases slightly. This contrasts with subalpine fir and Engelmann spruce and lodgepole pine trends for Management Areas 1 and 2. Within Management Area 3 the scale of disturbance is proportional to Management Areas 1 and 2, but the addition of silviculture treatments increases the pace of restoration. Grand fir composition trends down toward desired conditions within the cool moist type for all alternatives except Alternative Z. Within the warm dry broad potential vegetation type group, Ponderosa pine composition is increased, and grand fir is decreasing, each trending toward desired conditions. Within the warm moist broad potential vegetation type group, all species are trending toward the desired ranges, and grand fir composition is reduced to a greater extent for Alternatives W, X, Y, and the Preferred Alternative. As with Management Area 2, achieving desired conditions for dominance type is largely a function of the number of acres that can be treated per decade and the availability of seral seed sources.

Attainment of desired conditions for the primary seral species of whitebark pine, Western white pine, Western larch, and Ponderosa pine will require a restoration strategy that focuses not only on retaining these species where they occur but increasing species composition through artificial regeneration. This process requires time to produce results with an expected 70 to 100 years to achieve desired conditions under the proposed management strategies specific to each alternative.

The consequences of not achieving desired conditions for dominance types is the continued dominance of grand fir, Douglas fir, lodgepole pine, and subalpine fir or Engelmann spruce. These species are most susceptible to mortality from root diseases, insects, and fire. Ultimately, the forest will not be as resilient to disturbance events until seral species dominance can be reestablished.

Desired conditions for all management areas include an increase in seral species composition and a decrease in climax species composition. Each alternative is designed to accomplish this objective through a combination of silvicultural thinning treatments and the use of wildland fire. Figure 17 illustrates the trends in achieving dominance of Ponderosa pine, whitebark pine, Western larch, and Western white pine across all alternatives. Each alternative achieves similar results relative to improving dominance of seral species. In the short term, Alternative X achieves the greatest increase in Ponderosa pine dominance. Both Alternative W and X achieve similar results in increasing Western larch and whitebark pine. In the long-term, the Preferred Alternative achieves the greatest increase in dominance for Ponderosa pine and Western larch. Alternative W achieves the greatest increase in Western white pine dominance with Alternatives X, Y, and the Preferred Alternative achieving similar results. All alternatives achieve similar results for whitebark pine dominance in the long-term. The Preferred Alternative achieves the overall best results relative to desired conditions for seral dominance.

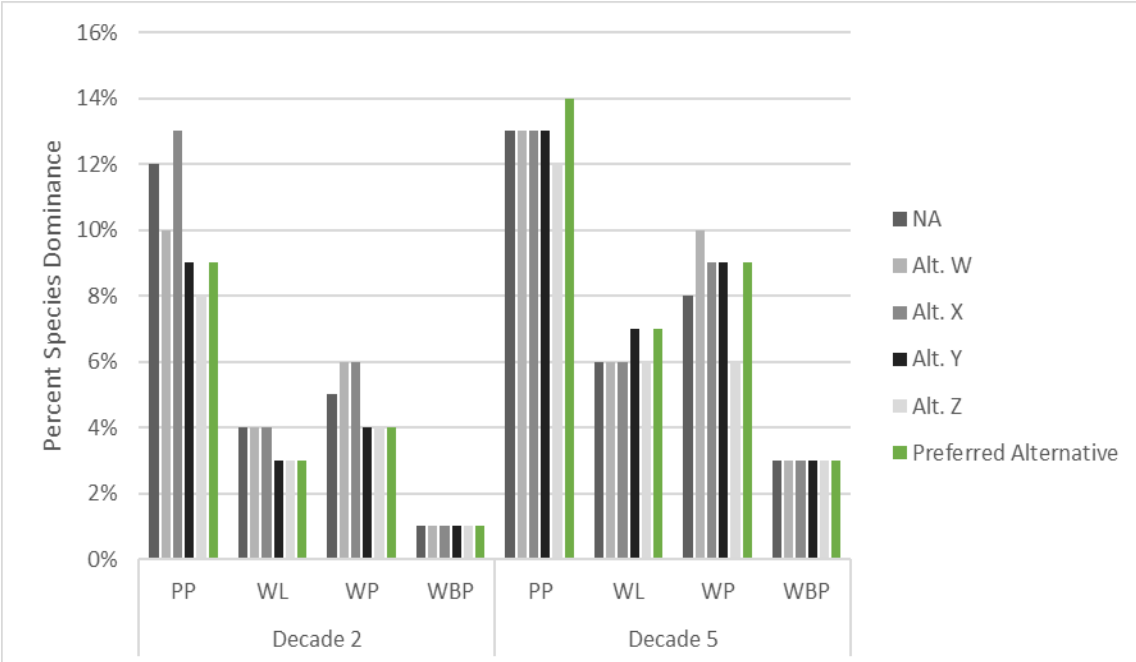

Figure 17. The 20-year and 50-year projects of seral species dominance by alternative.

Size class distribution

Size class distribution is an important indicator of forest structure, age class distribution, and affects the volume per acre of timber harvest. The ability to use wildland fire as well as effects from wildland fire are impacted by size class distribution. Snag and downed woody debris recruitment are affected by size class. Long-term sustainability of forested ecosystems requires a balanced size class distribution to promote structural diversity and natural regeneration. The following section describes size class distribution resulting from modeled alternatives for each management area. The extent to which size classes reach desired conditions is a measure of the desirability of the alternative for vegetation management.

The following tables show the extent to which forest vegetation trends toward desired size class distribution in each alternative. The tables are projections for both 20-year short term and 50-year long-term comparative periods for each alternative from the present and show the effect each alternative has on size class distribution by management area.

Size Class within Management Area 1

Management Area 1 is not subject to active forest management. Changes in size class distribution are the result of natural disturbance processes. The differences between alternatives are largely the result of differences in proposed wilderness designations, which are allocated from areas designated under the Idaho Roadless Rule in Management Area 2.

All action alternatives (W, X, Y, Z, and Preferred Alternative) indicate similar trends within Management Area 1, as shown in the following tables. Given that size class distribution is influenced through natural disturbance processes only, it is unlikely that desired conditions for size class distribution can be met within Management Area 1. The seral grass and forb size class is well over the desired range in the short term for all alternatives. In recent decades, Management Area 1 has experienced numerous wildland fires which tend to promote retention of larger diameter classes. This trend is consistent across all alternatives. Within Management Area 1, the seral grass and forb size class is both created and maintained through wildland fire.

Size Class within Management Area 2

Management area 2 is managed under the protocols identifies in the Idaho Roadless Rule. Active management of these lands is limited in both scope and scale. Only 1 percent of these lands are subject to mechanical vegetation management per year. Wildland fire is the primary management tool used to achieve desired conditions. The effects of the limited vegetation management approach are illustrated in the following tables. Similar trends are evident across all action alternatives.

[1]The 20” + inch DBH class contains stands with a plurality of very large diameter trees but also contains trees of small diameter classes.

Attainment of desired conditions for seral grass and shrub size classes is subject to the same natural disturbance regimes as discussed for Management Area 1. The percentage of very large (20+” DBH) size classes is on the upper end of desired conditions. Decline of the large size class by the end of the projection period is primarily due to much of the large size class growing into the very-large size class. The medium size class is limited and below desired conditions at the beginning of the projection period resulting in very little recruitment into the large size class. Abundance of very large size classes results, in part, from limited active vegetation management, effect of wildfire favoring survival of large diameter trees, dominance of grand fir, and ingrowth from the large size class.

Size Class within Management Area 3

Management Area 3 is the land area subject to active forest management strategies and includes all lands suitable for timber production. The seral grass and forb stage is maintained and described separately from the seedling or sapling size class to reflect the desire to maintain a portion of the forest as transitional forage to meet desired conditions for elk habitat. The seral grass and shrub stage is maintained during the early stages of stand development and then progresses through size class development. At the management area level, the desired ranges for size class are very broad. This reflects the differences between desired ranges at the broad potential vegetation type level and are discussed in the next section.

All alternatives including the No Action Alternative indicate similar trends in achieving desired conditions for size class for Management Area 3. Differences between alternatives are largely due to differing amounts of total suitable acres available for treatment and the pace of achieving desire conditions. At the Management Area level, all alternatives indicate size class distributions on the low end of desirable ranges for the 0–4.9 inch diameter at breast height (DBH) and 15–19.9 inch DBH dimeter classes. All alternatives are within the desired range for the pole size (5–14.9 inch DBH) and very large size classes by the end of the projection period.

Size class distribution at the broad potential vegetation type group level is more refined than that of the management area level, as shown in the following tables. This refinement is necessary to account for differences in species compositions between potential vegetation type groups and as well as differences in growth rates and response to disturbance. At the broad potential vegetation type level, all size classes are within desired ranges except for the warm moist and warm dry groups. Within the warm moist and warm dry groups all size classes are within desired ranges except for the very large class (20 inch + DBH) which is generally below the desired range.

Overall, the comparison between alternatives for size class distribution by potential vegetation type groups reveal modest variations. All alternatives indicate similar results for the grass or shrub, 0–4.9 inch diameter at breast height (DBH) class. For this class, percentages attained are all within the middle or on the upper end of the desired range for all management areas and potential vegetation type groups. The 10–14.9 inch DBH class is generally on the upper end of desired ranges for potential vegetation type groups across all alternatives. This reflects the effect of past timber harvest intensities and the projection of harvest intensities focused on reducing total stand density. Attainment of the 15–19.9 inch DBH class distribution is consistent between alternatives at the potential vegetation type group level and at the management area level. Differences in size class distribution between potential vegetation type groups is partly explained by the differences in species compositions and the rate at which large size class trees are growing into the very-large size class. The cold potential vegetation type group represents areas with shorter growing seasons than potential vegetation type groups at lower elevation zones. Slower growth rates result in a slower diameter progression. The cold potential vegetation type group is largely associated with Management Area 1 which is managed through natural processes only and not subject to thinning treatments which improve diameter growth. All alternatives indicate an increase of the very large (20 inch + DBH) class. At both the management area and potential vegetation type group scales the very large size class is within the lower bounds of the desired range.

The consequences of achieving diameter class distributions on the low end of the desired range is the potential delay in achieving harvest volume targets in the long term and delayed attainment of wildlife habitat conditions in the short term.

Canopy Cover Density

Canopy cover density is an important indicator of forest structure, forest resiliency, and disturbance regime. The ability to use prescribed fire, as well as the effects from wildland fire, are impacted by the percent and distribution of canopy cover. Long-term sustainability of forested ecosystems requires a mosaic of canopy cover densities at the landscape scale to promote heterogeneity in crown structure and to promote resilience to disturbance. Canopy cover density is a measure of area occupied by tree crowns in a horizontal plane across the landscape and is independent of size class. There are no specified desired conditions for canopy cover density. Canopy density is influenced by the site productivity of a given area, successional stage of the forest, climate regime, and disturbance history.

Trends for canopy cover density are consistent across all alternatives, as shown in the following tables. This suggests that natural disturbance patterns and frequencies are the largest driver of change for canopy cover density. The following table illustrates the extent to which forest vegetation trends toward the natural range of variation of canopy cover density classes. The table illustrates projections of 20–year short-term and 50–year long-term comparative periods from the present and shows the trend of canopy cover density by management area.

Table 81. Forestwide canopy cover density (existing condition) by broad potential vegetation type group.

Summary of Density

Canopy cover density trends for each management area are consistent across all alternatives. The scales and frequency of natural disturbance events such as wildfire and insect outbreaks have a greater effect on canopy cover density in Management Areas 1 and 2 than for Management Area 3. Modeled vegetation management treatments in Management Area 3 result in a greater proportion of open canopy cover densities compared to Management Areas 1 and 2.

Within Management Area 1, the existing condition for early seral stage is below the natural range of variation average and both open and closed densities are above. This condition reflects large scale disturbance events occurring in previous decades which have regenerated into high density stands and maintained as low density stands through continued disturbance. Management Area 1 is largely composed of spruce or fir and lodgepole pine dominance types which tend to regenerate into dense stands which are thinned through insect and disease vectors and small-scale high severity fires. By the end of the 50-year projection period, projected disturbance events result in the early seral stage exceeding the natural range of variation average, the open density class is below average, and the closed density class approximates the average. This pattern suggests a cycle in which canopy cover density increases following a disturbance and subsequently reduced through disturbance events toward an open density condition until additional disturbance promotes early seral conditions again.

Management Area 2 exhibits a similar trend to Management Area 1. The existing condition for early seral stage is below the natural range of variation average, closed densities are above the average, and open density strands approximate the average. By the end of the 50-year projection period, projected disturbance events result in the early seral stage exceeding the natural range of variation average, the open density class is below average, and the closed density class is above the average. This pattern suggests that early seral conditions have been created through disturbance and progressed into dense closed canopy cover density stands. By the end of the projection period, disturbance events have not reduced stands densities toward open canopy densities. Forest succession is dominated by natural events within Management Area 2 where vegetation management treatments are minimal. Management Area 2 is characterized as having both high severity and mixed severity fire regimes and dominance types which maintain closed canopy cover densities.

Management Area 3 exhibits trends below the natural range of variation average for early seral canopy cover density. By the end of the 50-year projection period, early seral density is only slightly above the average. Open canopy densities are below average at the beginning of the projection and trend toward the average by the end of the projection. Similarly, the closed canopy density is above average at the beginning of the projection and trend toward the average. Management Area 3 experiences disturbance events through both natural processes such as wildland fire, insect, and disease outbreaks as well as through vegetation management treatments. It is the emphasis of vegetation management practices which regulate canopy cover densities toward the natural range of variation averages.

Effects Common to Action Alternatives

All action alternatives contain Land Management Plan components for vegetation composition, structure, and pattern (Table 83). The Land Management Plan, which guides the action alternatives, would include the quantitative desired conditions presented in the affected environment section of this report, and as such terrestrial vegetation would be managed to be consistent with the natural range of variation and resilient to disturbance, with consideration for climate change vulnerabilities and adaptation options based on the best available science for the Nez Perce-Clearwater (Halofsky, Peterson, et al. 2018a, b). Consideration of other resource concerns may override attainment of desired conditions for vegetation. The components in the Land Management Plan that would guide management of terrestrial vegetation are summarized in the following table. This table is not all inclusive of plan components, which may have an impact on attainment of desired condition for terrestrial vegetation.

Table 83. Summary of plan components.

Plan Component	Summary of expected effects
FW-STD-ARINF-07	This plan component deals with construction and reconstruction of roads in the Conservation Watershed Network. This constraint may affect the ability to achieve desired conditions and limit economic viability of proposed projects.
FW-STD-RMZ-01	This plan component removes land from the timber production base, makes allowance for vegetation treatments within the outer zone of the riparian management zone to achieve aquatic restoration desired conditions, limits the use of non-mechanical treatments and prohibits the use of mechanical treatments.
FW-DC-EM-05	This energy and minerals plan component allows for the utilization of activity generated biomass which can be allocated to PWSQ attainment.
FW-STD-WL-01	This plan component limits the amount of lynx habitat available for treatment to reach dominant types and size class desired conditions; sets a limit on timber outputs that can be produced. Creates constraints to respond to insect and disease outbreaks.
FW-DC-WL-01-03, Wildlife	These plan components describe wildlife habitat niches relative to natural range of variation. This plan component may affect the spatial extent of vegetation management projects.
FW-DC-WL-04	This plan component deals with management of fisher habitats. Management options to respond to epidemic insect and disease outbreaks may be constrained. May affect ability to achieve desired conditions for dominance types, size class, and patch size.
FW-GDL-WLMU-03	This plan component deals with big game winter range and may affect mechanical operating seasons.
Suitability	Defines the land base suitable for timber production and affects the sustained yield limit. Effect attainment of dominance types; affects availability of firewood.
FW-DC-TBR-03	This plan component allows for the salvage of dead trees if trees are in excess of what is needed for wildlife objectives. Affects availability of firewood, affects project feasibility, ability to achieve dominance types and acres suitable for artificial regeneration.
FW-STD-TBR-04	This plan component allows for lower regeneration stocking than desired for long-term sustained yields and dominance type retention to achieve other resource objectives. This may affect forest density objectives, maintenance of dominance types and long-term sustained yield.

Plan Component	Summary of expected effects
FW-DC-FOR-03	This plan component defines desired ranges for species composition within the warm dry potential vegetation type group. This component applies to all management areas.
FW-DC-FOR-04, 07, 10 MA1-DC-FOR-09 MA2-DC-FOR-09 MA3-DC-FOR-07	These plan components define within-stand characteristics for each broad potential vegetation type group. Within-stand characteristics describe desired conditions for canopy layers (single story vs. multi story) and recruitment of legacy tree and large snags at the forestwide and management area level.
FW-DC-FOR-05, 08, 11 and 12	These plan components define the desired size class distribution forestwide for each management area and potential vegetation type group. These plan components also define the desired condition for the recruitment of large legacy trees as part of the desirable size class distribution.
FW-DC-FOR-03, 06, 09, 13	These plan components define the desired species composition forestwide for each management area and potential vegetation type group scales. Species composition is described as the percentage of desired dominance types for each potential vegetation type group.
MA3-DC-FOR-11 MA3-GDL-FOR-06 and 07 MA2-GDL-FOR-05 MA3-GDL-FOR-05	These plan components define the minimum number of snags by size class and minimum live tree retention required per unit area. Effects to attainment of forest vegetation objectives are not expected.
FW-DC-FOR-02, MA1-DC-FOR 01-04, MA2-DC-FOR-01-04, MA3-DC-FOR-(01,03,05,08)	These plan components define stand density requirements needed to achieve desired conditions for vigor, maintenance of early seral species dominance, and forest resiliency. Effects of this component allow for the attainment of desired conditions.
MA1-DC-FOR-05-08, MA2-DC-FOR-05-08, MA3-DC-FOR-(02,04,06,09)	These plan components define the landscape pattern, average patch size, and distribution of patches for the action alternatives. The desired effect is to increase the extent to which patches are consistent with historic processes.
FW-DC-FOR-01	This plan component established a minimum target of aspen restoration. The effects will be to increase composition of aspen on the landscape.
MA2-GDL-FOR-01 MA3-GDL-FOR-01	These plan components define the minimum amount of coarse down woody debris remaining post treatment to promote long-term soil productivity and habitat structure. The effect of this plan component will improve, maintain long-term soil productivity.
MA3-STD-FOR-01	This plan component constrains harvest within stands currently meeting old growth characteristics for defined old growth types unless such management will convert a non-resilient old growth type into a resilient type. Effects of this plan component are likely to maintain or slightly increase old growth retention acres across the Nez Perce-Clearwater.
MA2-DC-FOR-10 MA3-DC-FOR-10 MA2-GDL-FOR-02 – 04 MA3-GDL-FOR-02 - 04	These plan components provide a management and recruitment strategy for old growth forest cover types.
MA2-DC-RWILD-01-04, Recommended Wilderness	The desired condition plan components will likely limit attainment of forestwide and Management Area 2 vegetation desired conditions, remove lands where harvest may occur to achieve other resource objectives including salvage of timber and constrain options to manage insect and disease outbreaks.
MA2-GDL-E&SWSR-03,	These plan components describe the limitations to vegetation management resulting from this designation. The effect of this

Plan Component	Summary of expected effects
Eligible & Suitable Wild Scenic River	designation will be to limit attainment of desired conditions for riparian vegetation as well as maintenance of old growth forest types.
FW-DC-TE-1-6, Terrestrial Landscape	These plan components describe the desired condition of uncommon plant assemblages, ecotones, and riparian vegetation at the landscape scale.
FW-DC-GS-1-8, Meadows and Grasslands	These plan components describe the desired condition of non-forested vegetation at the landscape scale.
FW-GDL-GRZ-01, 02, 03 FW-OBJ-GS-01	These plan components provide for protection and improvement of native grasslands and meadows.
FW-DC-FIRE-01-03 FW-GDL-FIRE-01	These plan components describe the desired fire regimes, fuels profiles, and mitigation measures needed to achieve desired conditions. Achieving desired conditions for fire regimes is analogous to achieving desired conditions for vegetation.
FW-DC-INV-01 FW-GDL-INV-01, Invasive species	These plan components detail the desired conditions and management strategy of invasive weeds and plants. These plan components effect both forested and non-forested vegetation communities.
FW-DC-CARB-01, Carbon storage and sequestration	These plan components describe the nexus of the carbon cycle in the forested setting. Vegetation management will have a net positive effect on carbon sequestration at the ecoregion level.
FW-DC-SOIL-01-03 FW-STD-SOIL-01-03 FW-GDL-SOIL-01 AND 02 MA2 AND MA3-GDL-SOIL-01-03, Soils Resource	These plan components detail the desired conditions to maintain and improve soil productivity. These plan components promote the idea of mitigating soil disturbance from past disturbance events along with mitigation for proposed activities. These components may reduce economic viability of harvest operations. Vegetation management which allows for natural fire regimes which reduces uncharacteristic fire effects will promote long-term soil productivity.
FW-DC-WTR-02	This plan component describes connectivity of habitats between watersheds. This is the most significant constraint on attainment of vegetation desired conditions due to the proximity of many stream segments across the landscape.
FW-STD-WTR-04	This plan standard describes the instream habitat conditions for managed watersheds. Effects of management activities may be conflated with variations within reference conditions.
FW-STD-RMZ-01, Riparian Management Zone	This plan component constrains silviculture treatments within defined riparian management zone. The plan component may limit the effectiveness of vegetation treatments to achieve desired conditions for dominance types, old growth types, and size class distribution.
FW-STD-RMZ-04	This plan component constrains the cutting of personal use firewood within 150 feet of stream edge.
FW-DC-WLMU-04 and 06, Wildlife Multiple Use	These plan components describe the need to manage wildlife habitat within the natural range of variation. These plan components are not likely to have effects on achieving desired conditions for vegetation.
MA2-OBJ-WLMU-01-02, MA3-DC-WLMU-01, Wildlife Multiple Use	These plan components describe a minimum percentage of each management area that should be treated to achieve desired conditions for high quality elk forage. These high-quality forage areas are maintained through open stand conditions. They may affect achievement of desired conditions for dominance type, successional stage, and size class distribution, as well as long-term PTSQ, due to delay of target stand development on suitable timber production acres.
MA2-DC-IRA-01, Idaho Roadless Rule	These plan components comply with designation of lands under the Idaho Roadless Rule. The component is unlikely to allow for achievement of desired conditions for forest vegetation. The current

Plan Component	Summary of expected effects
	forest conditions are not functioning under the natural range of variation and can be expected to continue to experience uncharacteristic wildfire events and insect outbreaks.

Effects that Vary by Alternative

Ecosystem processes: projected wildfire

Wildfires are expected to have the most substantial influence on vegetation in the future. The expected acres of wildfire are generated by SIMPPLLE based on assumptions for fire suppression, future climate (warm and dry), vegetation conditions, and projected vegetation treatments (Figure 18). The differences in alternatives are a result of different land allocations, such as lands suitable for timber production, which influence the amount and type of vegetation management that is projected to occur. These differences resulted in only subtle variation in projected wildfire acres across the alternatives.

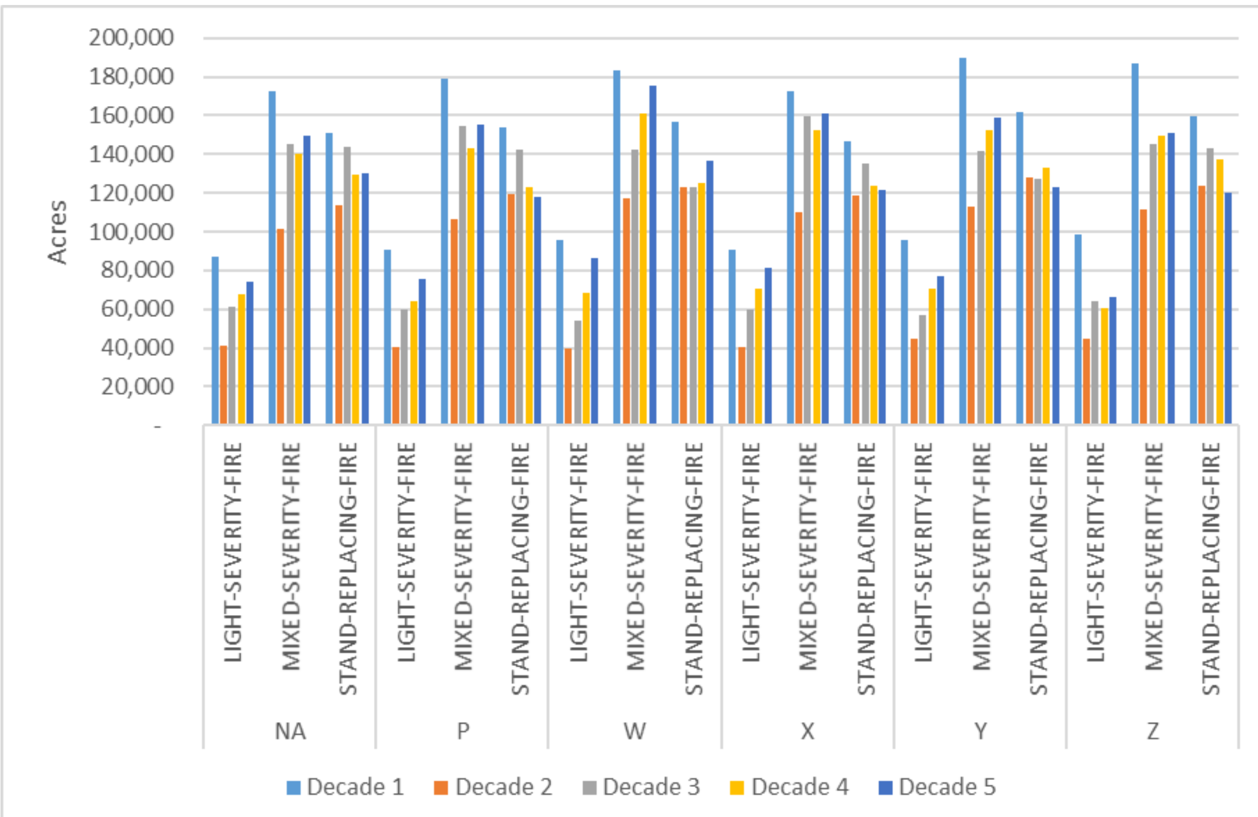

Figure 18. Projected average acres affected by future wildfire per decade, by alternative.

Data Source: SIMPPLLE

Though our best understanding of how fire behaves and its effects on vegetation were used to inform the model, there is an inherent degree of uncertainty. We cannot predict with high accuracy where and when fires will occur. There is a high degree of variation, spatially and temporally, in the amount and location of fire. The average wildfire acres displayed in the figure below do not imply an "even flow" of acres burned over time. The acres burned vary by decade between the simulations. As shown in Appendix B, the estimated mean levels of wildfire activity are below the natural range of variation for low severity fires and at the low end but within the natural range of variation for mixed severity and stand replacing fires at the forestwide landscape scale. As discussed in previous sections, different fire regimes give rise to different vegetations patterns and patch sizes, forest densities, species compositions, and size class distributions of species across the landscape. The resulting mosaic of forest conditions promotes forest resiliency and diversity.

Ecosystem processes: projected insect and disease activity and hazard ratings

Insects and disease will also play a substantial role in vegetation change over the next five decades. The amount of insect and disease disturbance is closely tied to the abundance of the host species, vegetative succession of forests into susceptible conditions (that is, larger trees and higher densities), and warmer climates. Figure 19 shows modeled estimates of future insect activity; all alternatives show nearly identical trends. Mountain pine beetle is projected to have the largest impact compared to other insect agents. The sharp increase in beetle activity from decade 1 to decade 2 is the result of populations of lodgepole pine growing into susceptible size and stand density classes. As lodgepole pine populations decline toward the natural range of variation, so does the number of acres with high beetle hazard ratings. Data is not available to generate a beetle hazard rating estimate for whitebark pine. It is reasonable to conclude that in areas where lodgepole pine and whitebark pine populations overlap or are in close proximity, whitebark pine are more likely to be affected by mountain pine beetle.

As shown in Appendix B, the estimated mean levels of Douglas fir beetle are within the natural range of variation. Mountain pine beetle would also generally be within its natural range of variation, except on cold broad potential vegetation types where the model predicts infestations above the historic amount. This indicates continued impacts to whitebark pine and lodgepole pine from this insect.

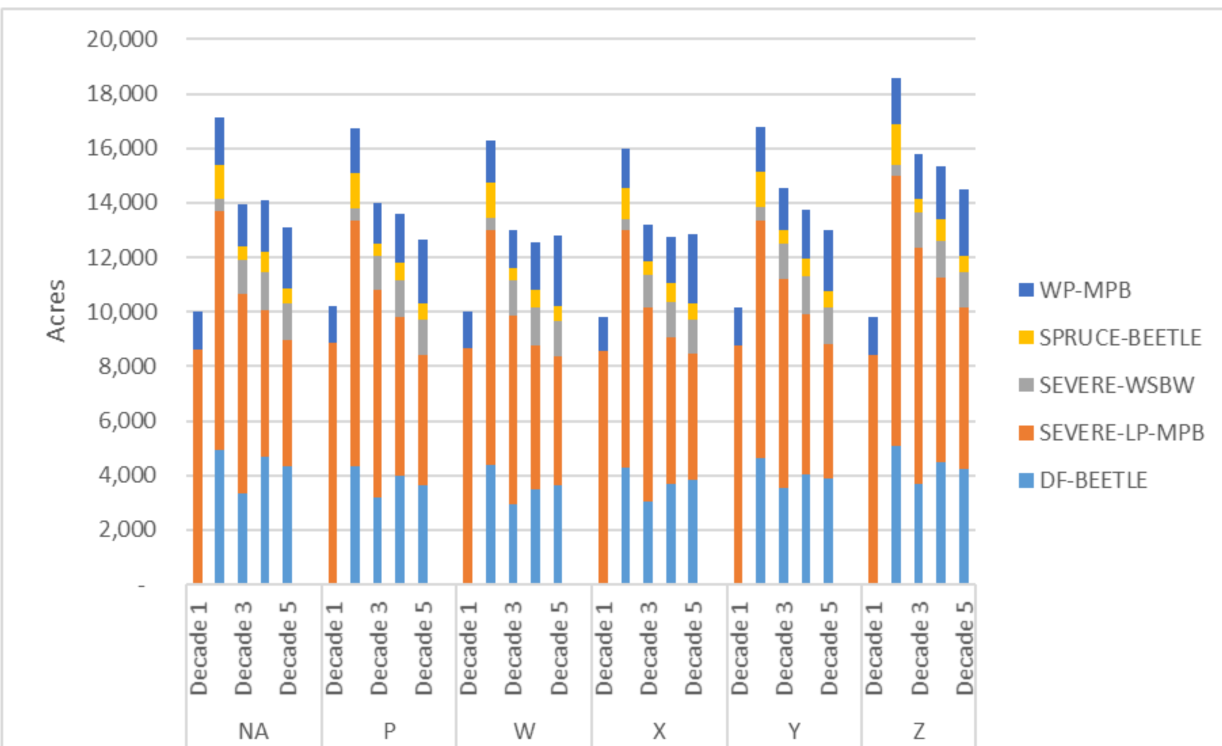

Figure 19. Projected average acres affected by insects per decade by alternative.

WP-MPB=Western white pine-mountain pine beetle. WSBW=Western spruce budworm. LP-MPB=lodgepole pine-mountain pine beetle. DF=Douglas fir beetle.

Data Source: SIMPPLLE model

The modeling suggests that in all alternatives, the hazard to bark beetles will decrease over time at the forestwide scale; this partly reflects a gradual decline in composition of host species. It is also likely a function of the anticipated distribution of density and diameter classes across the forest which promotes variability in stand structure for host species.

Figure 20 illustrates the projected impact of root disease at the forestwide scale. As discussed in previous sections, root disease is the second largest disturbance agent affecting forested vegetation compared to wildland fire. The trend across all alternatives toward increasing light and high hazard root disease ratings reflects the continued prevalence of host species at the landscape scale. Increases from decade to decade reflect both expansion of existing root disease pockets and development of new root disease pockets resulting from the continued dominance of host species. Douglas fir and grand fir composition remains above the natural range of variation for all projected decades.

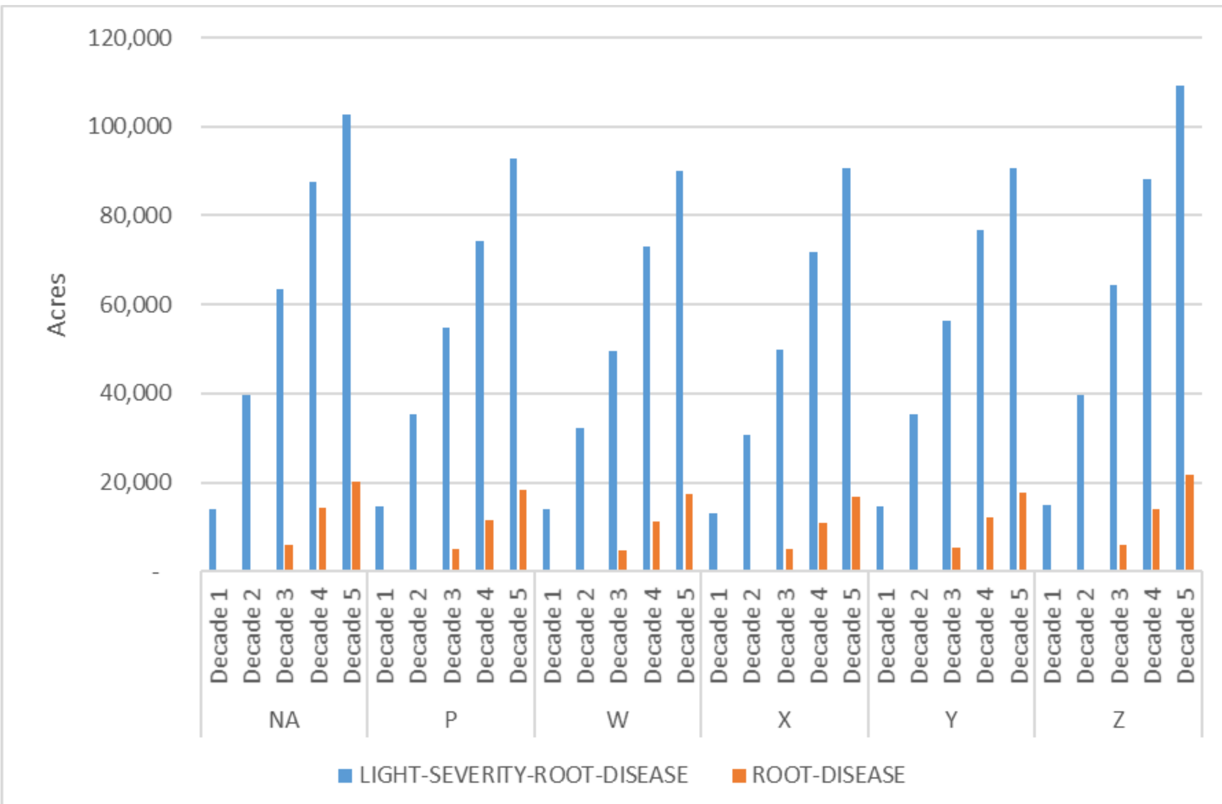

Figure 20. Acres with light and high severity hazard of root disease by alternative.

Note that high severity root disease is labeled only ‘root-disease’ in the graph.
Data Source: SIMPPLLE model

Effects from Other Resources

Timber Harvest

Timber harvest is one of the tools available to change vegetation for purposes of maintaining or moving towards desired vegetation conditions. Land Management Plan direction guiding timber harvest is provided in all alternatives. The PRISM model was used to generate the best solution for applying future timber harvest to move towards desired conditions while considering resource constraints and management guidance for each alternative. Refer to the Timber section and Appendix B for more information. The acres influenced by timber harvest are a relatively small proportion of disturbance compared to natural disturbance processes such as wildfire.

The suitability analysis is summarized in Figure 21, and detailed in Appendix B. This analysis reveals only modest differences between alternatives. Alternative X has the most land determined to be suitable for timber production, while the No Action Alternative contains the least by a factor of approximately 1 percent. These are lands where harvest would be used to the greatest extent, although all alternatives include lands that are unsuitable for timber production where harvest can occur for other purposes (timber harvest allowed). Alternative X contains the largest number of unsuitable acres where timber harvest is allowed. These lands are within the roadless area associated with Management Area 2. Alternative W contains the most unsuitable lands and Alternative X the least. This reflects the difference between existing wilderness designations associated with Alternative X and the combination of existing designated wilderness and recommended wilderness associated with Alternative W. Timber suitability for the Preferred Alternative falls approximately half-way between Alternative W and X. The difference between all alternatives in terms of timber suitability is less than 1.5 percent.

	No-Action Alternative	Alt. W	Alt. X	Alt. Y	Alt. Z	Preferred Alternative
Suitable Lands	1,028,480	1,041,522	1,043,959	1,029,983	1,037,058	1,042,520
Unsuitable Lands Harvest Allowed	528,577	382,688	606,971	578,690	517,246	586,014
Unsuitable Lands	2,381,999	2,514,846	2,288,127	2,330,384	2,384,752	2,310,523

Figure 21. Total acres by timber harvest suitability class and alternative.

Data Source: TimberSuitability20200923.xlsx.

Figure 22 displays the projected acres of timber harvest by management area on lands both suitable and unsuitable for timber production. Estimates are based on the PRISM analysis assuming a reasonably foreseeable budget and displayed for both short-term (2 decades) and long-term (5 decades) for each alternative. The No Action Alternative treats the fewest acres compared to the action alternatives. Alternative W treats the most acres through the third decade. Timber harvest within Management Area 2 is confined to acres suitable for timber harvest.

Figure 23 illustrates the total acres treated within each potential vegetation type group for both short and long-term projections. The warm moist potential vegetation type group has the largest amount of harvest which coincides with also having the most acres of all potential vegetation type groups.

All alternatives would treat more of the landscape with even-aged regeneration harvest than with other types of harvest (intermediate or uneven-aged systems). This proportion remains static over time but with varying amounts of prescribed burning. Prescribed burning is the primary tool used to achieve desired conditions in Management Area 2. These trends are based on the model finding the optimum solution to move the landscape towards desired conditions. Even-aged regeneration harvests are likely driven by the desired condition to alter species composition (most notably, the desired condition to increase dominance types for seral species) whereas other types of harvest may be more related to altering forest structures (most notably, the desired condition to increase large size classes).

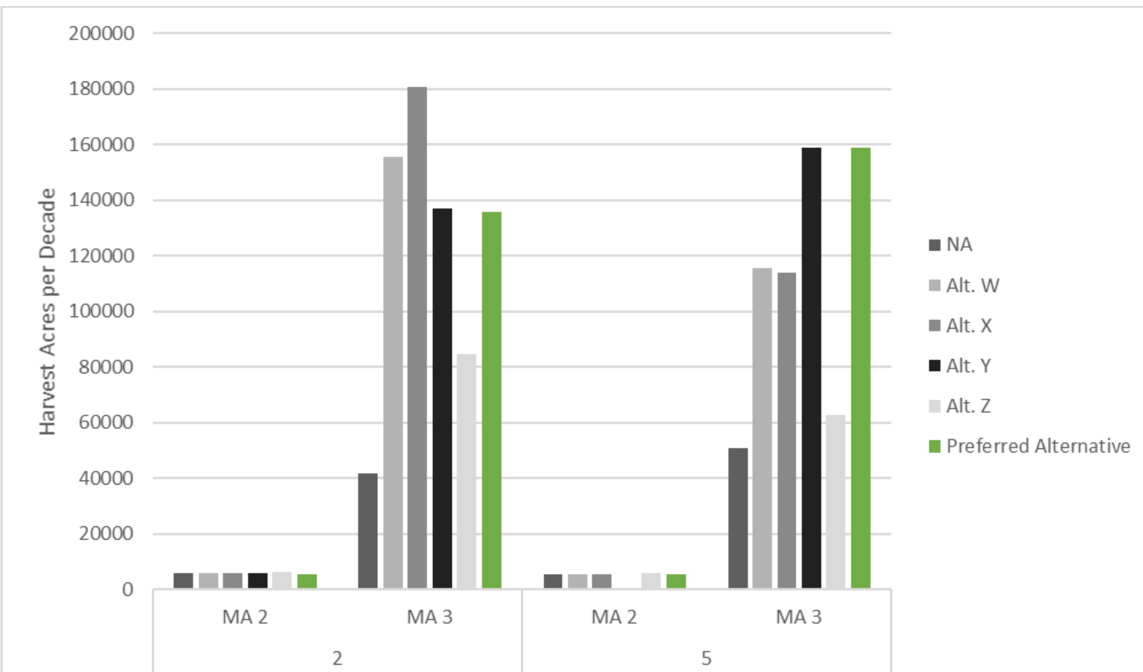

Figure 22. 20-year and 50-year predicted total acres harvested by management area and alternative under a reasonably foreseeable budget. Y-axis labeled in decades.

Data Source: Treatment_Tables_Graphs.xlsx.

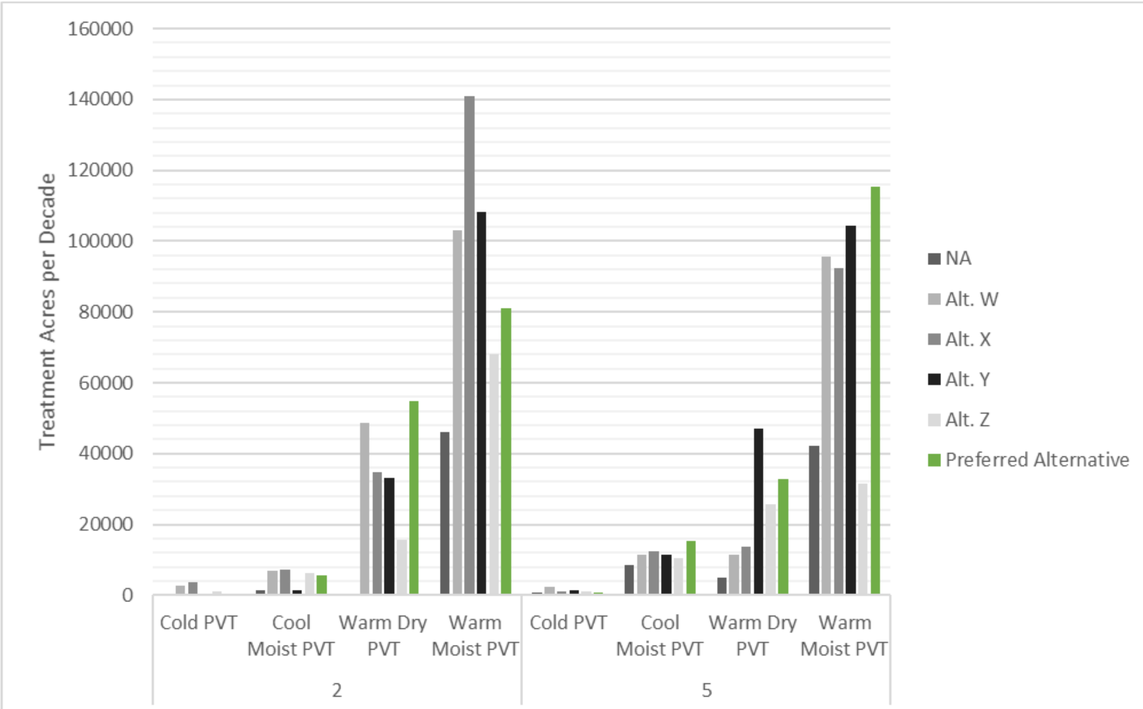

Figure 23. 20-year and 50-year predicted total acres harvested by potential vegetation type and alterative. Y-axis labeled in decades.

Data Source: Treatment_Tables_Graphs.xlsx.

As noted in the Timber section, across all action alternatives, the PRISM model generally selected warm moist forests for harvest treatment to best meet the desired conditions as defined by dominance type, density class, and size class distributions. The warm dry potential vegetation type group was also selected by the model to achieve desired conditions for Ponderosa pine. Alternatives W, X, Y, and the Preferred Alternative would generally do more to move warm moist forests toward more open densities and seral species dominance than Alternative Z and the No Action Alternative.

As shown in the Landscape Resiliency vegetation pattern section above, average patch sizes are projected to increase over time, specifically in the cool moist broad potential vegetation type. This may result in average patch sizes that trend toward the natural range of variation and desired condition. The Land Management Plan includes standards for maximum even-aged harvest openings based on the natural range of variation, for all alternatives. For all broad potential vegetation type groups, the maximum forestwide average patch size is 207 acres, which is consistent with the desired condition ranges as well as the broad-scale average patch size projected through time. This maximum patch size desired condition represents the average patch size under natural range of variation conditions. As such, it approximates the mean projected patch size but is aligned with the natural range of variation. This average patch size represents all forest disturbances resulting in an opening classified as either seedling or sapling size class or transitional forest. Therefore, to the extent that timber harvest affects the landscape, larger patch sizes may promote early successional stages and help to maintain stable dominance type communities. Patch size was not a variable included in the desired conditions for timber modeling (PRISM) but would be a consideration during implementation of the plan under any alternative. The No Action Alternative would result in a maximum opening size of 40 acres for all potential vegetation types (with exceptions as provided by law).

Regeneration harvest would alter forest size class, primarily resulting in seedling or sapling forests. Reforestation (planting or natural regeneration) would occur in these stands and can be used to achieve desired conditions for species composition. Other harvests include intermediate treatments or thinning. These treatments primarily reduce tree density but may also increase size class (when smaller trees are removed) and can change forest composition. Uneven-aged harvest tends to maintain or increase the shade tolerant tree species as compared to shade intolerant species, because of the small openings and denser forest canopy conditions but can also be used to promote uneven-aged stands of intolerant species such as Ponderosa pine. The projected harvest acres and subsequent vegetation changes produced by the PRISM model are incorporated into the SIMPPLLE model, and therefore their influence on the indicators for terrestrial vegetation are reflected in the results shown in this report.

Salvage Harvest

Under any alternative, salvage harvest may occur in burned areas or those infested with insects or disease, removing a portion of the dead trees for their economic value. The potential for this activity is not modeled. In practice, the term salvage is technically only applied as an intermediate harvest; in the case of stand replacing disturbance the cutting of dead trees is termed as a clearcut, seed tree, or shelterwood harvest as appropriate. However, the term "salvage" is used here more broadly to indicate any post-disturbance harvesting. Most land within the Nez Perce-Clearwater is in wilderness, recommended wilderness, or inventoried roadless areas where harvest, including salvage, would be prohibited or greatly limited and natural disturbances would be predominant, including wildfire that creates abundant burned forest conditions. Salvage would most commonly occur in lands suitable for timber production. Relative to terrestrial vegetation, the impacts of salvage would generally be consistent with a "green" harvest in terms of trees removed and reforestation, because the full suite of plan components that guide timber harvest would apply. The ecological effects of post-fire logging are influenced by various combinations and intensities of the fire itself and management activities that affect (1) ground disturbance by equipment and road use; (2) number of living and dead trees and their spatial pattern following harvest; (3) postharvest fuel treatment; and (4) in some cases, grass seeding and placement of various structures and materials to mitigate the effects of fire and logging (Peterson, Agee, et al. 2009). Post-fire harvest may fit into an effective restoration strategy if management pathways for attaining desired combinations of species, forest structure, and ecological functions are specified.

Fire and Fuels Management

Fire and fuels management provide tools to help achieve vegetation desired conditions and therefore generally result in positive impacts to terrestrial vegetation. Wildland fire can be the only feasible management option in landscapes where mechanical treatments are not allowed or are infeasible, such as Management Area 1 and Management Area 2. The objectives for fuel reduction are usually complementary to other desired vegetation conditions, especially related to forest resiliency. Plan components that allow for wildland fire and other fuel reduction activities exist in all alternatives. Management direction for the action alternatives emphasizes and provides greater flexibility in the use of wildland fire to improve vegetative conditions. The revised plan components are designed to recognize the natural role of fire on the landscape and its importance in shaping the ecosystem, while also protecting values at risk.

The PRISM model was used to generate the best solution for applying future prescribed fire to move towards desired conditions while considering resource constraints and management guidance for each alternative. These treatments were only applied in forested lands because that is the focus of PRISM modeling. In actual practice, additional prescribed burning in non-forested vegetation types would also occur. In the model, prescribed burning treatments were applied both as maintenance treatments within harvested stands, as well as stand-alone prescriptions. Figure 24 displays the average acres of projected prescribed burning by alternative for short term and long-term comparative periods. These projections are for comparison purposes only; the ability to achieve burning on the ground is highly uncertain and dependent upon many factors including weather windows. The PRISM model projects that under all alternatives; prescribed fire is utilized to a greater extent within Management Area 2 and 3 than in Management Area 1.

Within the PRISM modeling exercise, the number of acres treated with only prescribed fire is directly proportional to the number of acres treated through timber harvest only. As timber harvest increases, the number of wildland fire acres decreases. However, in terms of total acres treated, prescribed fire will remain the dominant treatment method at the landscape scale. At the project scale, timber harvest and prescribed fire are used in combination to achieve desired conditions. Attainment of desired conditions for dominance type, size class, and density require periodic removal or reduction in the number of late seral species components as well as stand densities. The tool used to accomplish desired conditions is largely a function of management area constraints and the management intensity required to achieve vegetation management objectives. Figure 25 presents the number of acres treated by prescribed fire by potential vegetation type group.

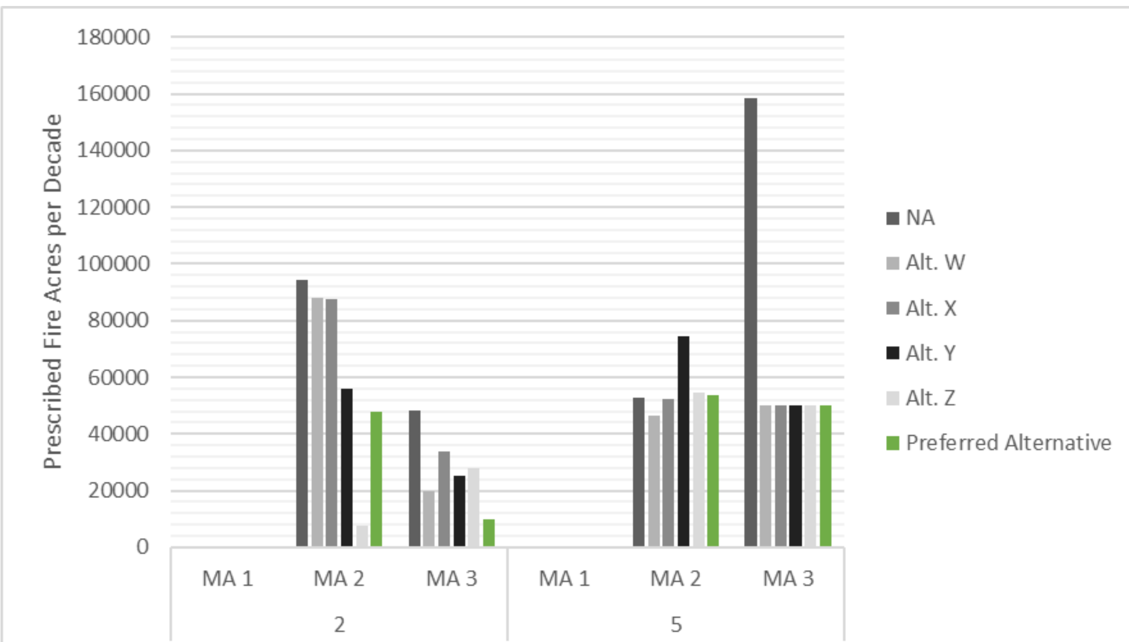

Figure 24. The 20-year and 50-year projected total prescribed burning acres by management area and alterative, under a reasonably foreseeable budget. The Y axis is labeled in decades.

Data Source: Treatment_Tables_Graphs.xlsx

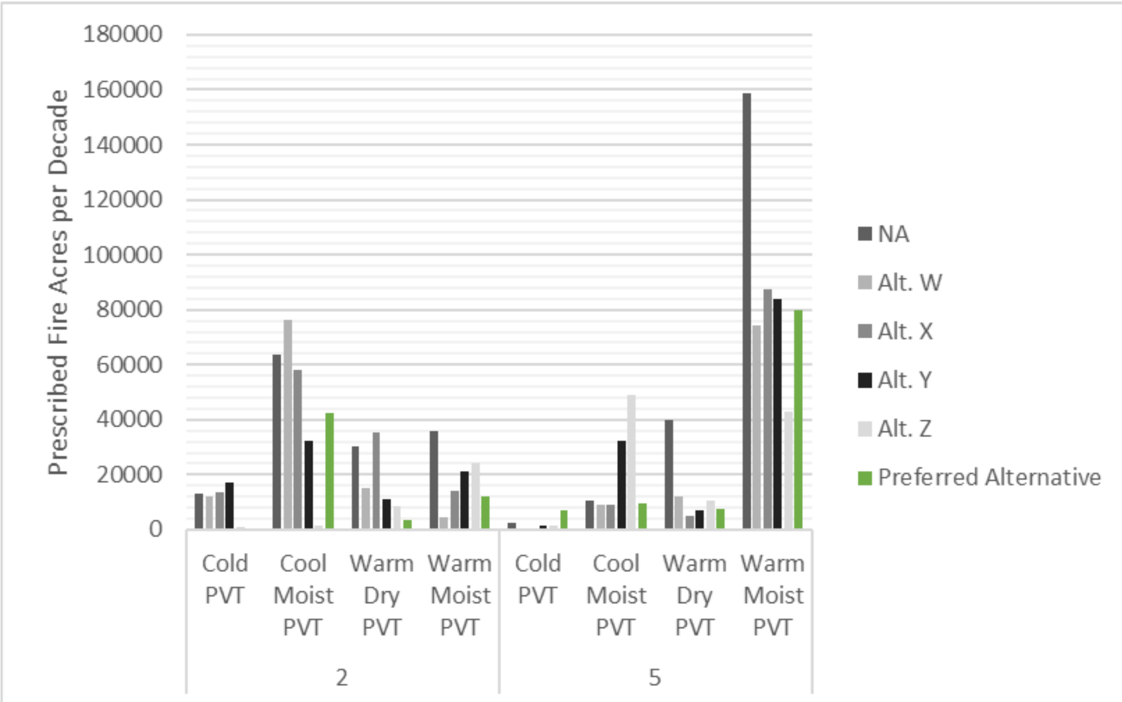

Figure 25. The 20-year and 50-year projected total prescribed burning in broad potential vegetation types by alterative, under a reasonably foreseeable budget. The Y axis is labeled in decades.

Data Source: Treatment_Tables_Graphs.xlsx

All alternatives apply greater amounts of prescribed fire to the warm moist potential vegetation type group than any other group. This is in response to the need to convert young stands dominated by grand fir into stands dominated by seral dominance types.

The effects from prescribed fire depend greatly on the vegetation type. For example, low severity underburning would be generally applied in the warm dry and, to a lesser extent, in the warm moist broad potential vegetation groups, where early successional fire-resistant species occur. The results would be more open forests with more fire tolerant species composition, and larger size classes as the smaller trees are killed by fire. Moderate to high severity burns would be applied in the warm moist, cool moist, and cold broad potential vegetation groups; in these areas, the result may be creation of seedling or sapling size classes, reduced densities, altered species composition, or increased size class. In non-forested vegetation types, fire would generally serve to maintain the dominance of grass and shrubs by killing small conifer encroachment, while possibly promoting and maintaining large, scattered trees in savanna areas. It would also stimulate the growth and vigor of many fire-adapted plants, while others would be killed in the short term.

In lands within the wildland urban interface and near communities, there would likely be a continued emphasis on fire suppression, although the action alternatives would allow for managing wildland fire on all areas when appropriate. Although both prescribed fire and other fuels treatments may occur across the landscape to achieve desired conditions, in the wildland urban interface in particular, it is likely that mechanical treatment methods would be needed in conjunction with prescribed fire to reduce hazardous fuels and create conditions conducive to more safe and effective suppression efforts. To achieve desired fuel conditions, there may be areas where forest conditions are created and maintained over the long term at lower densities, that is, very open and park-like conditions. This would be consistent with the natural disturbance regime found on many sites, such as in the warm dry potential vegetation group. However, in cases where cool moist forest types are found in the wildland urban interface the site-specific conditions could be more open than what would occur under natural disturbance regimes. This effect is common to all alternatives.

Recreation Opportunity Settings

Recreation opportunity settings are defined for all alternatives. The array of recreation opportunity Spectrum settings varies by each action alternative and influence both the potential access and type of vegetation treatments that can occur, particularly timber harvest as described in the Timber section. Alternative Z is most limiting to harvest in this regard, as it includes the most primitive and semi-primitive non-motorized settings. Alternative X is the least limiting, as it includes the most semi-primitive motorized and roaded natural settings, which are compatible with timber harvest and lands suitable for timber production.

Scenery

Under all alternatives, plan components associated with scenery may affect terrestrial vegetation through their influence on allowable vegetation treatments that could help move vegetation towards desired conditions. The magnitude and type of vegetation treatment (particularly timber harvest) in areas with higher scenic values may be limited. Effects to scenery are typically localized and would be determined in project-level analysis; in some landscapes, scenery plan components may align perfectly with terrestrial vegetation desired conditions, while in other landscapes these components may inhibit or delay achievement of desired vegetation conditions. However, because both vegetation and scenery objectives emphasize retaining or mimicking conditions that are consistent with natural processes, at the broad scale plan components related to scenery and visual quality would not likely preclude the achievement of desired conditions for terrestrial vegetation. The No Action Alternative uses visual quality objectives to define scenery management, whereas the action alternatives utilize scenic integrity objectives. Scenic integrity objectives offer greater flexibility and recognition of natural disturbance regimes and vegetation conditions. Alternative Z is most potentially limiting to vegetation management activities, as it has the most numerous high and very high scenic integrity objectives because of having the most recommended wilderness and primitive recreation opportunities. Alternative Y is the least limiting. Refer to the Timber section.

General Wildlife Management

Wildlife plan components under all alternatives would influence terrestrial vegetation management. In the existing forest plans, many of these elements are blended into management area guidance, and some complement terrestrial vegetation desired conditions as described in previous tables. For the most part, plan components for wildlife under the action alternatives are complementary to those of terrestrial vegetation. By design, the desired conditions for vegetation would benefit and provide for the wildlife habitat conditions that support the full suite of native species. This is the coarse-filter approach to providing ecological integrity.

Elk Management

Under all alternatives, the management of elk habitat is commensurate with managing for vegetation desired conditions. Management of elk habitat is focused on four components, including improved nutrition, distance from open motorized access, habitat use in context of elk use of slopes, and vegetation interspersion. Plan components do not vary by alternative or management area. The potential influences of elk management plan components cannot be explicitly modeled and quantified with PRISM or SIMPPLLE models but can be inferred from vegetation management plan components and modeled vegetation response to management.

Elk management plan components focused on improved nutrition are not likely to restrict timber harvest. Plan components influence the selection of treatment locations and the distribution of treatments focused on areas with the highest potential to produce high quality forage for elk. Management guidelines focused on access management are driven more specifically by forest level travel management decisions than road systems developed for timber harvest units. Most roads utilized for timber harvest unit access are temporary roads, which may or may not be accessible to the public. Elk management guidelines may influence the construction of new road segments proposed for timber access relative to location and closure status.

Given the scale of analysis for ecosystem restoration projects, elk management components focused on topographic position of elk habitats are not likely to influence decisions related to location of timber harvest units. Forestwide vegetation plan components are focused on moving vegetation towards desired conditions across all broad potential vegetation type groups located on all topographic positions. Arrangement of harvest units on the landscape are intended to reflect landscape forest patterns and variation in patch size resulting from the natural fire regime. Elk management components focused on vegetation interspersion are compatible with vegetation management components.

Canada Lynx Management

All alternatives would incorporate the Northern Rockies Lynx Management Direction (U.S. Department of Agriculture 2007e), which would influence vegetation management and how desired conditions are applied in potential lynx habitat (roughly 20% of the Nez Perce-Clearwater). Refer to Appendix H of the Land Management Plan for the lynx plan components. Although the management direction applies to mapped occupied lynx habitat, the guidance should be considered on all mapped habitat on the national forest, including habitat that is currently considered unoccupied. Occupied lynx habitat was identified in the 2006 Amended Canada Lynx Conservation Agreement by the United States Forest Service and United States Fish and Wildlife Service, and currently includes only Management Area 1. However, because the guidance should be considered on all lands, and there is potential for occupied habitat to change, lynx management direction is applied and analyzed across the entire Nez Perce-Clearwater for forest planning purposes.

Several of the objectives of the lynx direction complement the terrestrial vegetation plan components by describing a desired condition to manage vegetation to approximate natural succession and disturbance processes (#1) and provide a mosaic of habitat conditions through time (#2). Further, objective #4 specifically points to the opportunity to utilize vegetation management to promote the development of desirable habitat characteristics.

Several standards and guidelines may potentially impact the management of terrestrial vegetation (VEG-S1, S2, S5, and S6). These standards include an exemption for fuel reduction treatments within the wildland urban interface, and exceptions to these standards may also occur for pre-commercial thinning to benefit other resources. The acres affected for S1, S2, S5, and S6 cumulatively must occur on no more than 6 percent of mapped lynx habitat. The number of acres that may be treated in the wildland urban interface by exemption or pre-commercially thinned by exception are determined in consultation between the Forest Service and the United States Fish and Wildlife Service; maximum acres that may be affected are defined for the Nez Perce and Clearwater National Forests separately as part of an Incidental Take Statement. Treatments that are conducted under the exemptions and exceptions are monitored. To date, over the 10 years since the adoption of the final lynx direction, the exemption or exceptions have been applied to less than 22 acres of mapped occupied habitat across the Nez Perce-Clearwater, which represents a small percentage of the allowable threshold.

The limitations of the lynx management direction were incorporated into the PRISM model, and therefore their influence is incorporated into the results displayed in this report. The effects tied to each standard individually are assessed in the following subsections.

Northern Rockies Lynx Management Direction Standard VEG-S1 and S2

Standards VEG S1 and S2 would potentially limit the amount of regeneration harvest that may occur. Standard VEG S1 requires that if more than 30 percent of the lynx habitat in a lynx analysis unit is currently in a stand initiation structural stage that does not yet provide hare habitat during winter, no additional habitat may be regenerated by vegetation management. Standard VEG S2 requires that timber management shall not regenerate more than 15 percent of lynx habitat on National Forest System lands in a lynx analysis unit in a 10-year period. These standards may limit potential vegetation treatments in some areas where seedling or sapling forests are abundant, particularly after a stand replacing disturbance. However, in those instances it is likely that the desired vegetation conditions would be consistent with not creating additional regenerating forest patches. Therefore, these standards should be complementary or at least not preclude the potential future achievement of terrestrial vegetation desired conditions.

Northern Rockies Lynx Management Direction Standard VEG-S5

Standard VEG S5 does not allow pre-commercial thinning that reduces snowshoe hare habitat in seedling or sapling size stands except in very limited situations. In addition to the exemption or exceptions allowed in the wildland urban interface previously described, other exceptions are provided for pre-commercial thinning within 200 feet of administrative buildings (#1); thinning for research studies or genetic tests (#2); thinning associated with aspen (#4); or whitebark pine restoration (#6). Finally, an additional exception (#3) is provided to allow for thinning based on new information that is peer reviewed and accepted at the regional level; however, this analysis and documentation does not yet exist.

This standard may reduce the effectiveness of achieving desired vegetation conditions across portions of the forest, as shown in the following tables. Although dense forests may be desired in some stands, in many others, pre-commercial thinning can be used to trend forests towards desired composition, densities, size classes, and improved resilience over time, especially in lands suitable for timber production. Early thinning can be more cost effective at achieving these goals than waiting until the trees are larger and more difficult to process. The following tables provide an illustration of the magnitude of the effect of standard VEG S5 on potential pre-commercial thinning opportunities.

Table 84. Seedling/sapling forests in potential lynx habitat in Management Area 1.

Option	Lynx Habitat (acres)	Seedling/Sapling Size Class	% Total Acres
No Action Alternative	617,798	90,429	14.6%
Alternative W	617,798	90,429	14.6%
Alternative X	617,798	90,429	14.6%
Alternative Y	617,798	90,429	14.6%
Alternative Z	617,798	90,429	14.6%
Preferred Alternative	617,798	90,429	14.6%

Table 85. Seedling/sapling forests in potential lynx habitat (both occupied and unoccupied) in Management Area 2.

Option	Lynx Habitat (acres)	Seedling/Sapling Size Class	% Total Acres
No Action Alternative	622,823	97,863	15.7%
Alternative W	622,228	97,863	15.7%
Alternative X	621,497	97,863	15.7%

Option	Lynx Habitat (acres)	Seedling/Sapling Size Class	% Total Acres
Alternative Y	622,672	97,863	15.7%
Alternative Z	625,947	97,863	15.6%
Preferred Alternative	622,239	97,863	15.7%

Table 86. Seedling/sapling forests in potential lynx habitat (both occupied and unoccupied) in lands suitable for timber production within Management Area 3.

Option	Lynx Habitat (acres)	Seedling/Sapling Size Class	% Total Acres
No Action Alternative	247,479	91,752	37.1%
Alternative W	248,074	91,752	37.0%
Alternative X	248,805	91,752	36.9%
Alternative Y	247,630	91,752	37.0%
Alternative Z	244,355	91,752	37.5%
Preferred Alternative	248,063	91,752	36.9%

The majority of lynx habitat is located within Management Areas 1 and 2 for all alternatives. Acres of lynx habitat within Management Area 3 have the highest percentage of acres in the smaller diameter classes.

The proportion of the lands suitable for timber production in a seedling or sapling size class within potential lynx habitat represent lands where pre-commercial thinning would most commonly be desired, and conversely that action would be delayed by lynx management direction. Pre-commercial thinning could not occur until the stands no longer provide habitat for snowshoe hare, that is, after the trees self-prune and no longer include green limbs that touch the snow surface in the winter. Hand thinning is generally most feasible and cost-effective when the trees in the stand are small, and therefore delaying treatment may render the action infeasible, and the opportunity to improve stand growth and quality could be foregone in some areas. The number of acres in this condition is consistent across all alternatives. Such areas that still provide snowshoe hare habitat could only be pre-commercially thinned if exception #3 can be met in the future through new peer-reviewed written documentation.

Pre-commercial thinning would not be feasible or needed in all of these young stands, depending on the site specific existing and desired conditions, nor would current or anticipated budget levels support thinning all these acres.

Northern Rockies Lynx Management Direction Standard VEG-S6
Except for the exemption for fuels treatments in the wildland urban interface (as described above), standard VEG S6 does not allow vegetation management that reduces winter snowshoe hare habitat in mature multi-story forests. This habitat condition most commonly develops on the cool moist and cold broad potential vegetation types in common with lynx habitats. Other exceptions are provided for treatments within 200 feet of administrative buildings, dwellings, outbuildings, recreation sites, and special use permits including ski areas (#1); treatments for research studies or genetic tests (#2); or for incidental removal during salvage harvest (#3). VEG S6 also notes that timber harvest could be used to create openings to improve hare habitat in stands with poorly developed understories.

Mature multi-storied hare habitat is common and currently comprises not less than 30 percent of the potential lynx habitat area across the Nez Perce-Clearwater. This amount will fluctuate over time as the condition is removed by disturbance and develops in other stands. Under all alternatives, the SIMPPLLE model predicts the amount of multistory habitat to increase for the first few decades (to nearly 40 percent of the potential lynx habitat area forestwide) and then decrease again to about 30 percent of the potential lynx habitat area forestwide by decade 5. Therefore, this standard is likely to be more limiting in the future than in the current condition, with any alternative.

Adhering to VEG S6 would result in harvest and prescribed fire treatments rarely being feasible in multi-story mature forests in potential lynx habitat due to the likely damage to understory trees. This limitation would limit vegetation management to the greatest extent in potential lynx habitat outside of the wildland urban interface, which represents roughly 34 percent of the Nez Perce-Clearwater in all alternatives. Much of this area is in inventoried roadless, recommended wilderness, or designated wilderness areas where the only vegetation treatments that could occur would be prescribed fire.

VEG S6 would potentially reduce or delay the ability to achieve desired vegetation conditions in some areas, such as increasing the abundance and resilience of whitebark pine. The inability to apply vegetation management in whitebark pine forests where fire exclusion has allowed spruce or fir canopy layers to develop would result in foregoing some whitebark pine restoration opportunities; refer also to the At-Risk Plant Species section. In addition, achieving resiliency through management in other stands by promoting early seral species (such as Western white pine) or more open tree canopies would not occur in mature multi-storied stands that intersect lynx habitat.

Mature multi-story hare habitat is likely to be susceptible to high severity fire as well as to damage and mortality from Western spruce budworm, bark beetles, and other agents. Therefore, vegetation management to promote the development of future mature multi-storied hare habitat, as allowed in VEG S6, may be warranted in some areas. This guidance would influence the types of prescriptions selected in some projects (that is, selecting uneven-aged management to promote the development of spruce or fir multi-storied stands, rather than another vegetation treatment that would promote other structures or species).

At the broad scale, the promotion of mature multi-storied forest is an important piece of the desired vegetation mosaic. VEG S6 would not necessarily preclude a trend towards other terrestrial vegetation desired conditions, in large part because vegetation treatments are predicted to influence a relatively minor proportion of the landscape. Still, this standard may have some impact on the potential to achieve specific desired conditions related to lodgepole pine and whitebark pine forests. The vegetation modeling included parameters that did not allow timber harvest or prescribed fire within existing mature multi-storied stands in potential lynx habitat. While this condition currently represents only about 20 percent of the forests on the cool moist and cold broad potential vegetation types, the amount is predicted to increase over time. The model also predicted a decrease in the lodgepole pine cover type and a fairly static trend for whitebark pine, along with increases in spruce or fir on the cool moist and cold broad potential vegetation types. Therefore, VEG S6 may become increasingly limiting in the future and represent some tradeoffs with the potential to achieve other desired conditions through active management.

Under any alternative, the achievement of desired vegetation conditions and lynx habitat would require integration of the full suite of desired conditions for a given landscape, and appropriately assigning vegetation management in time and space.

Fisher Management

Fisher habitat management applies to Alternative Z and the Preferred Alternative only. Fisher habitat generally follows distribution of warm moist potential vegetation type (even though fishers sometimes use other potential vegetation types). Fisher habitat is composed of large patches of tall forest (trees ≥ 25 m tall, see glossary) arranged in complex, highly connected patterns at landscape scale (20–40 sq mi). Patches of tall forest cover an extent of approximately 50 percent across warm moist potential vegetation type group forestwide (consistent with desired conditions in warm moist potential vegetation type section, Table 68). At the home range scale (8 sq mi), fishers benefit from variety in successional stages resulting from patchy mosaic of stand heights that occur in patterns that reflects natural disturbance (see Warm Moist potential vegetation type). The shapes, sizes, distribution, density, and height of forest patches vary by topography, slope, aspect, and topographic position (for example, ridge, mid-slope, toe slope, valley bottom) to provide variety in fisher habitat (for example, seasonal habitats, denning, foraging). Some stands of tall forests, distributed across the warm moist potential vegetation type, provide a high prevalence of large trees and snags (20 inch + DBH), abundant coarse woody debris, and multiple canopy layers (denning and resting habitat). Desired condition is based upon best available science (Sauder and Rachlow 2014, Sauder 2014), however it may be adjusted in the future by new science that produces improved understanding of fisher habitat. Table 87 illustrates the number of acres within Management Area 3 that are classified as potential fisher habitat. Approximately 65 percent of the Management Area 3 is classified as potential fisher habitat.

Table 87. Comparison of Management Area 3 fisher habitat acres under Alternative Z and the Preferred Alternative.

Option	Fisher Habitat Total Acres	Fisher Habitat Total MA3 Acres	% MA3 with Potential Fisher Habitat
Alternative Z	1,233,180	806,261	65
Preferred Alternative	1,240,340	806,261	65

Limitations of the fisher management direction were incorporated into the PRISM model, and therefore their influence is incorporated into the results displayed in this section.

Plan component FW-DC-WL-04, may reduce the effectiveness of achieving desired vegetation conditions within the warm moist potential vegetation type group associated with Management Area 3. Although large patches of mature forests may be desired in some stands, in many others multi-canopy stands composed of younger age classes can be used to trend forests towards desired composition, densities, size classes, and improved resilience over time, especially in lands suitable for timber production. This may be particularly important for converting late successional cover types such as grand fir toward an early successional stage composed of seral species. However, promoting Western redcedar dominance types is an example of achieving both desired conditions for terrestrial vegetation and maintain fisher habitat.

Watershed and Conservation Watershed Management

Watershed plan components exist for all alternatives but are more specific in the action alternatives than in the No Action Alternative. One way that watershed plan components would influence terrestrial vegetation is through their constraint on potential timber harvest; refer to the Timber section (FW-STD-TBR-03), Conservation Watershed Networks and the Water Resources sections. Watershed plan components may also either limit or encourage other forms of vegetation management, such as prescribed fire and tree planting, to maintain the appropriate level and types of vegetation cover that reduce erosion potential as well as the risk of uncharacteristic fire effects. These components are not built on the concepts of the natural range of variation and, therefore, would not complement or may preclude the achievement of the terrestrial vegetation desired conditions as described in this report. The management direction found in the action alternatives recognizes more flexibility in potential scenarios related to vegetation and natural disturbances than the No Action Alternative.

Soils Management

Under all alternatives, plan components related to soils would generally benefit terrestrial vegetation by ensuring that soil productivity is maintained in the long-term. Standards and guidelines related to soils may limit vegetation management activities, such as timber harvest and prescribed fire, by restricting activities, timing, or conditions that may be detrimental to soils. The action alternatives provide greater specificity in the standards and guides for soils than the No Action Alternative, particularly with respect to allowable detrimental disturbance and post-treatment ground cover and coarse woody debris requirements.

Aquatic Habitat and Riparian Management

Measures to protect aquatic habitat and riparian areas apply under all alternatives near streams, water bodies, and wetlands, as well as upland segments between streams. Riparian management zones are defined differently depending on the alternative, as described in the Water Resources, Aquatic Ecosystems and Fisheries, and Soil Resources sections. Plan components would limit and guide the type, amount, and location of vegetation treatments that have the potential to impact riparian resources, as well as requiring retention of trees and other forest components. Refer to the Timber section. As with conservation watershed network plan components, desired conditions for aquatic habitat and riparian areas are not based on a natural range of variation analysis. Many plan components have been developed to ensure a variety of forest activities are designed to protect, enhance, or restore riparian and aquatic resources to promote recovery of endangered fisheries.

Riparian management zones are narrow, linear features on the landscape that help provide for wildlife habitat connectivity, late successional forest features, and refugia for seed sources; therefore, plan components that encourage the retention of these features would generally complement terrestrial vegetation desired conditions. All action alternatives recognize that vegetation treatments, including prescribed fire, within riparian management zones may be beneficial and needed to achieve desired conditions and provides direction to increase efficiency and flexibility for managing in certain areas within riparian management zones, as determined through site-specific analysis. Though vegetation treatments in riparian management zones are not prohibited in the existing Forest Plan, the No Action Alternative does not provide clear direction or flexibility, and thus could be more limiting on the ability to trend forest towards desired conditions.

Recommended Wilderness Area Management

The alternatives vary in the quantity and location of recommended wilderness areas, ranging from none in Alternative X, to 856,932 acres in Alternative W. The extent to which recommended wilderness impacts forestwide management strategies vary greatly between alternatives. Alternative W has the largest percentage of land (51 percent) allocated to both wilderness and recommended wilderness, while Alternative X has the lowest at 29 percent. The Preferred Alternative has 35 percent of land area designated as either wilderness or recommended wilderness. Recommended wilderness areas are currently designated as roadless areas under the Idaho Roadless Rule. Within these areas, all action alternatives would have the same level of ability to achieve desired vegetation conditions within recommended wilderness areas using vegetation treatments. All have Land Management Plan direction that allow restoration activities to occur if the ecological and social characteristics that provide the basis for wilderness recommendation are maintained and protected. Anticipated vegetation treatment activities would largely be associated with restoration of Western white pine in the warm moist broad potential vegetation type groups and whitebark pine forest communities occurring in high elevation ecosystems. There may be other treatments occurring to achieve restoration objectives outlined in the plan components. The most likely treatment would be prescribed burning (planned ignition), in some cases followed by limited planting of conifer seedlings. Objectives would include restoration of desired forest structure and compositions, and to restore desired landscape patterns.

Future wilderness designation from recommended wilderness areas is not likely over the life of the land management plan. However, new wilderness designations would result in reduced flexibility and options for vegetation management to achieve desired conditions compared to the existing land use designation. Desired conditions for recommended wilderness would be achieved through wildland fire and natural disturbance processes only. The opportunity to maintain and restore whitebark pine would be very limited.

Suitable Wild and Scenic Rivers

The action alternatives vary in the quantity and location of suitable wild and scenic rivers, ranging from none in Alternative X to 166,176 acres in Alternative Z and 183,808 acres under the No Action alternative. For the No Action Alternative, the existing identified wild and scenic rivers are eligible for designation. Wild and scenic river suitability, as well as designation, are distinguished by three separate categories: wild, scenic, and recreational. For suitable wild river corridors, cutting of trees and other vegetation is not allowed within the corridor except when needed to maintain a primitive recreation experience, to protect users, or to protect outstandingly remarkable values. Wildland fire may be used to restore or maintain habitat for threatened, endangered, or sensitive species or to restore the natural range of variation. For suitable scenic and recreational river corridors, a range of vegetation management treatments are allowed within the corridor if these practices are designed to protect users, or protect, restore, or enhance the river environment and its outstandingly remarkable values.

Eligible and suitable wild and scenic river corridors are mainly located in Management Area 2 and would be managed under the vegetation management restrictions associated with such designations. Within these areas, desired conditions for vegetation would be obtained primarily through natural disturbance processes. Scenic and recreational river corridors across the action alternatives would have the same level of ability to achieve desired vegetation conditions using vegetation treatments. Scenic and recreation river corridors have Land Management Plan direction that allow restoration activities to occur if the ecological and social characteristics that provide the basis for scenic and recreational recommendation are maintained and protected. Anticipated vegetation treatment activities would largely be associated with the restoration of highly departed vegetation conditions or in response to disturbance events which have compromised the integrity of management objectives. There may be other treatments occurring to achieve restoration objectives outlined in the plan components. The most likely treatment would be prescribed burning (planned ignition), in some cases, followed by limited planting of conifer seedlings. Objectives would include restoration of desired forest structure and compositions and to restore desired landscape patterns.

Future wild and scenic river designation areas could be anticipated. Determination of suitability for wild and scenic river designation would likely result in reduced flexibility and options for vegetation management to achieve desired conditions.

Cumulative Effects

The effects that past activities have had on all of the components of forest vegetation (for example, forest composition and structure, landscape pattern, etc.) were discussed in the Affected Environment section and are reflected in the current condition of the forest vegetation. Therefore, unless otherwise noted, past activities are not carried forward into the following cumulative effects analysis. In addition, the Measurement Indicators section above that discusses consequences to vegetation from Land Management

Plan components associated with other resource programs is a form of cumulative effects analysis. Present and foreseeable future activities that could affect forest vegetation are summarized below.

Changing human populations

Human populations are projected to increase adjacent to the plan area which will likely result in additional stressors to the ecological systems of the Nez Perce-Clearwater. Increasing population levels, both locally and nationally, increase demands and pressures on public lands. Refer to the Social and Economics sections. As related to forest and vegetation conditions, these changes may lead to increased demands for commercial and non-commercial forest products, elevated importance of public lands in providing for habitat needs of wildlife species, and changing societal desires related to the mix of uses public lands are expected to provide.

Management of Adjacent Lands

Portions of the Nez Perce-Clearwater adjoin other national forests, each having its own forest plan. The Nez Perce-Clearwater is also intermixed with lands of other ownerships, including private lands, other federal lands, and state lands. Some management areas contain inholdings of such lands, while others are more contiguous in terms of ownership.

Harvesting or conversion of forests on adjacent lands would affect vegetation conditions at the landscape level, changing forest composition and structures. Idaho Forest Practices regulations apply to all harvest activities regardless of ownership; therefore, basic resource protections would be consistent. However, harvest practices on other lands would not necessarily be conducted to meet the same desired conditions as those outlined in the Nez Perce-Clearwater Land Management Plan. Forest pattern (patch sizes, shapes) would potentially be affected by treatments on non-National Forest Service (NFS) lands immediately adjacent to NFS lands. Forest conditions on adjacent lands may influence pattern, extent, or intensity of natural disturbances within forests on NFS lands, for example fuel conditions and fire hazard or potential spread of insect and pathogen populations. Forest conditions on NFS lands will be important for their contribution to maintaining desired biodiversity at the broad landscape scale.

Adjacent lands are subject to land management under their own resource management plans. The cumulative effects of these plans in conjunction with the Nez Perce-Clearwater Land Management Plan are summarized in Table 88. Summaries of applicable terrestrial vegetation are provided for each land management plan.

Table 88. Summary of cumulative effects to terrestrial vegetation from other resource management plans.

Resource plan	Description and Summary of effects
Adjacent National Forest Plans	The forest plans (or land management plans) for National Forest System lands adjacent to the Nez Perce-Clearwater include the Idaho Panhandle, Payette, Wallowa-Whitman, Bitterroot, and Lolo National Forests. All plans deal with terrestrial vegetation. Management of vegetation is consistent across all national forests due to law, regulation, and policy. The cumulative effect would be that the management of vegetation would be generally complementary.
Idaho Forest Practices Act (1974) and State of Idaho Forest Practices Water Quality Management Plan (1988)	This act and associated management plans guide forest management on state endowment lands. It includes many concepts that are complementary to plan components for the Nez Perce-Clearwater, for example promoting forest resilience, providing wildlife habitat, and reducing hazardous fuels. While specific desired conditions are not stated in the same terms as the Nez Perce-Clearwater, it is likely that some elements such as increasing

Resource plan	Description and Summary of effects
	large trees, early seral species, and open forests would be similar. State forest lands may be actively managed to a greater degree than national forest system lands and would likely contribute to achievement of desired vegetation conditions across the landscape.
Nez Perce Tribe Forestry and Fire Management Plan (https://nezperceforestryandfire.com/forestry/)	The Nez Perce Tribe manages some 770,000 acres of tribal trust lands in north and central Idaho; a portion of which is adjacent to the Nez Perce-Clearwater. The Nez Perce Forest Management Plan provides for economically, socially, and environmentally sustainable forest management of tribal lands. The Nez Perce Tribe forest management strategy is complementary to the Land Management Plan components.
U.S. Army Corps of Engineers, Walla Walla District, Dworshak Five Year Vegetation Management Plan (2015-2020) (U.S. Army Corps of Engineers 2015)	The U.S. Army Corps of Engineers manages approximately 29,318 acres of forest land surrounding Dworshak Reservoir and another 1,760 acres of flowage easement located on the Nez Perce-Clearwater. The Corps management plan includes vegetation in accordance with ecosystem management principles to improve forest health and elk habitat, while maintaining protection of important resources and adhering to federal land management regulations. This ecosystem management approach is complementary to vegetation management proposed in the Nez Perce-Clearwater forest plan.
Idaho State Parks and Recreation Strategic Plan (Idaho Department of Parks and Recreation 2018)	These plans guide the management of state parks, some of which lie nearby or adjacent to national forest system lands. Terrestrial vegetation is a component of these parks, although not always the primary feature. Specific vegetation conditions would not necessarily contribute to the desired conditions as described for the Nez Perce-Clearwater.
Idaho State Wildlife Action Plan (Idaho Department of Fish and Game 2017b)	This plan describes a variety of vegetation conditions related to habitat for specific wildlife species. This plan would likely result in the preservation of these habitats on state lands, specifically wildlife management areas. This plan would interact with the Idaho Statewide Forest Resource Strategy (above). The vegetation conditions described would be complementary to the conditions being managed for with the Nez Perce-Clearwater Land Management Plan.
County wildfire protection plans	Some county wildfire protection plans map and define the wildland urban interface. The Nez Perce-Clearwater notes that these areas may be a focus for hazardous fuels reduction, and other plan components (such as Northern Rockies Lynx Management Direction) have guidance specific to these areas. Managing for open forests and fire adapted species may be particularly emphasized in these areas. Overall, the effect of the county plans would be to influence where treatments occur to contribute to desired vegetation conditions.
Private Industrial Forest Management Companies	Private industrial forest management companies have land holdings adjacent to lands administered by the Nez Perce-Clearwater. Private industrial lands are generally managed to produce the highest economic return on investment. At the landscape scale these lands typically represent forest communities which are maintained in early successional stages and are managed to minimize insect and disease occurrence. While these lands are not typically managed for multiple ecosystem services, they are managed for long-term sustained yield of forest products. As such, management of these lands is not contradictory to plan components of the Nez Perce-Clearwater Land Management Plan.

Effects to Resource from Other Resources

Climate Change

Refer to the Climate Change and Forest Carbon Section and Appendix G – Climate Change and Carbon for a broader discussion of climate change and potential effects to forested ecosystems.

Livestock Grazing

In all alternatives, livestock grazing would occur on portions of the Nez Perce-Clearwater within designated livestock grazing allotments. Plan components would enable grazing activities to complement terrestrial vegetation management. While grazing and trampling from livestock can damage native plants and tree seedlings and saplings, plan components are in place that would ensure that grazing is managed to promote sustainable and vigorous native plant communities. Further, components are in place that would ensure that grazing does not adversely impact the regeneration of forests, or re-seeding of non-forested areas with desirable native vegetation. Plan components would strive for desired conditions for grasslands, meadows, and riparian areas.

Air Quality

The consequences to terrestrial vegetation from air quality related Land Management Plan direction are the same for all alternatives. All alternatives have direction to meet air quality standards established by federal and state agencies and meet the requirements of state implementation plans and smoke management plans. The direction limits how much can be burned and when and where it can occur. The costs of conducting prescribed fires increases because of burning regulations and inflation over time, which affect how much is burned. The ability to implement the vegetation treatments that would occur because of the alternatives is dependent upon prescribed burning as well as using natural, unplanned ignitions to meet resource objectives. Therefore, to the extent that air quality regulations may become more stringent in regard to the quantity and timing of smoke emissions, there could be limitations to conducting prescribed burning.

Mining and Mineral Extraction

Mining undergoes site-specific National Environmental Protection Agency analysis to determine effects and required mitigation, and effects to vegetation from mining is determined at the project level. Generally, the impacts to terrestrial vegetation from mineral extraction on the forest are localized and insignificant at the forestwide scale Refer to the Energy and Minerals section (Chapter 3.5.2) for a broader discussion of effects.

Summary of Consequences

This forestlands analysis is designed to evaluate the effectiveness of Land Management Plan components to achieve or move toward desired conditions developed for forest vegetation. Desired conditions for forested vegetation are informed by the natural range of variation for specific forest metrics. Desired conditions for forest vegetation were developed through an interdisciplinary process to account for multiple resource needs, concerns, and objectives. This process is intended to purposely interweave desired conditions for vegetation with desired conditions for wildlife habitat.

Selected measurement indicators are used to compare the effectiveness of each alternative to achieve or move toward six key ecosystem characteristics. This relationship is illustrated in Table 89 which is reproduced here for ease of comparison. No weighting criteria is applied to the rankings. Each ecosystem characteristic is given equal weight in the analysis to promote objectivity and to simplify comparisons.

Table 89. Ecosystem characteristics, measurement indicators, and measures.

Ecosystem Characteristic	Measurement Indicator	Measure
Vegetation composition	Dominance types	Percent of area
Size class distribution	NTG classes (based on basal area weighted diameter)	Percent of area
Forest density	Classes based on canopy cover density	Percent of area
Landscape resilience	Resilience indicators	Insect and disease hazard ratings
Landscape resilience	Resilience indicators	Projected wildland fire
Landscape resilience	Resilience indicators	Landscape pattern/patch size
Rare/Unique habitat elements	Aspen prevalence	Percent of area
Old growth	Resilient old growth	Percent of area

No single alternative achieves the highest level of desired condition containment for all measurement indicators (Table 90). Overall, the Preferred Alternative achieves the highest level of attainment of desired conditions. Alternatives W, X, Y, and the Preferred Alternative are generally very close in overall performance. The No Action Alternative and Alternative Z clearly performed below the other action alternatives. This comparative analysis validates the selection of the Preferred Alternative as an effective strategy for attainment of vegetation desired conditions.

Table 90. Forestlands summary of consequences by alternative.

Measurement Indicator	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Dominance Types	Low	High	High	Moderate	Low	Moderate
Size Class Distribution	Low	Low	Moderate	Low	Moderate	High
Forest Density	Low	Moderate	Moderate	High	Low	High
Landscape Resilience	Moderate	High	Low	Low	Moderate	Moderate
Rare/Unique habitats	Moderate	Moderate	High	Moderate	Low	Low
Old Growth	High	Low	Low	Moderate	High	Moderate

Data Source: Summary Ranking.xlsx.

Conclusion

The following key points summarize the conclusions for terrestrial vegetation:

Broadly, desired conditions are characterized by increases in the very large forest size classes, reduction in closed canopy forest densities within Management Area 3 and vigorous non-forested plant communities and increasing early-seral shade intolerant species as compared to the existing condition while maintaining the full range of biodiversity on the landscape. These conditions are consistent with the modeled natural range of variation and most likely to be resilient in the future.

Expected trends for terrestrial vegetation forestwide show little to no variance across alternatives, due to the limited scope and impact of vegetation management treatments at the landscape scale. Effects of vegetation treatments are masked by the effects of natural disturbances.

Total acres of prescribed burning required to achieve desired conditions are attainable based on reasonably foreseeable budgets.

Modeling of future conditions predicts increases in Ponderosa pine, Western white pine, Western larch and whitebark pine along with decreases in grand fir and Douglas fir across all broad potential vegetation types on most landscapes; reductions in lodgepole pine and increase in spruce or fir on cool moist and cold potential vegetation types are predicted.

Modeling of future conditions predicts increases in the seedling or sapling, medium and very large size classes, and reductions in the large size class. The total area composed of grass or forb stage is also reduced in Management Area 3 as forest succession proceeds.

Modeling of future conditions predicts increases in the low to medium density class along with reductions in the high-density class within Management Area 3, as well as reductions in single-storied forests and increases in multi-storied forests. The opposite trend is predicted to occur within Management Areas 1 and 2.

Modeling of future conditions indicates a trend toward increased patch size and average area weighted mean patch size, thus increasing the percentage of early successional forests, and reducing the effects of fragmentation.

A variety of plan components will ensure non-forested areas, particularly riparian areas, meadows, and grasslands, are managed for protection and enhancement of associated plant communities.

3.2.2 At-Risk Plant Species

This section presents potential impacts on at-risk plant species from plan components and from management actions from other resource programs. Species reviewed are federally listed or species that are formally proposed or candidates for listing; Nez Perce-Clearwater service species of conservation concern are listed under direction of the 2012 Planning Rule or are on the present U.S. Forest Service Northern Region Forester's sensitive species list. The Nez Perce-Clearwater has a legal requirement to maintain or improve habitat conditions for species federally listed under the Endangered Species Act by the U.S. Fish and Wildlife Service. Management actions that disturb habitats, disrupt soil surfaces, or otherwise contribute to impacts on at-risk species within a particular portion of the Nez Perce-Clearwater could affect the capacity of that landscape to support the species. The Nez Perce-Clearwater is required to identify and mitigate potential effects to these species from land-disturbing actions to comply with the Endangered Species Act and agency policies.

Rare plants contribute to the diversity of plant communities based on the suitability and capability of the landscape to contribute to overall multiple use objectives of the National Forest Management Act. They also contribute to recreational opportunities for rare plant enthusiasts and scientific researchers for the multiple use of resources and benefits to people.

Rare plant species occur throughout the Nez Perce-Clearwater, but sites of high representation and general floral diversity occur in areas of coastal disjunction in the low elevations of the larger Clearwater Basin tributaries, larger grassland complexes, and arid non-forest habitats that form islands in the general mesic forest types. The flora of the Salmon River axis and high Bitterroots are less known due to reduced access and little past project level analysis.

Relevant Laws, Regulations, and Policy

Federal Laws

Endangered Species Act. Requires federal agencies to protect and recover threatened and endangered species.

The National Forest Management Act of 1976 states it is the policy of U.S. Congress that plans shall provide for the diversity of plant and animal communities based on the suitability and capability of the specific land area to meet the overall multiple-use objectives.

Agency Regulations

36 CFR 219.9 states that the responsible official will evaluate whether the plan components provide the ecological conditions necessary to contribute to the recovery of federally listed species, conserve proposed and candidate species, and maintain a viable population of species of conservation concern in the plan area. Evaluation would consider components that provide for ecosystem integrity and diversity and species-specific components.

Policy

The Forest Service Manual (FSM) contains legal authorities, objectives, policies, responsibilities, instructions, and guidance needed on a continuing basis by Forest Service line officers and primary staff in more than one unit to plan and execute assigned programs and activities.

Forest Service Handbooks (FSH) are the principal source of specialized guidance and instruction for carrying out the direction issued in the Forest Service Manual.

FSH 1909.12.5. The directives provide specific information regarding implementation of the 2012 Planning Rule, including identifying at-risk species and guidance for development of plan components for at-risk species and to provide ecological sustainability. The directives state that plan components developed for ecosystem integrity are expected to provide conditions that will maintain the persistence or contribute to the recovery of native species within the plan area. They also state that if components for ecosystem diversity are not adequate to do that for at-risk species, then species-specific plan components should be developed.

FSM 2670.5. Defines sensitive species as those plant and animal species identified by the Regional Forester for which population viability is a concern, as evidenced by significant current or predicted downward trends in population numbers, density, or habitat capability that reduce a species' existing distribution. Under the 2012 Planning Rule, species of concern will replace sensitive species, but sensitive species must be included in planning analysis as such until the new Land Management Plan is enacted.

FSM 2670.22. Directs management for sensitive species to ensure that species do not become threatened or endangered because of Forest Service actions and to maintain viable populations of all native species.

Methodology

Spatial Scale

The geographic scope of the analysis for effects to rare plants is the lands administered by the Nez Perce-Clearwater. This area represents the National Forest System lands where changes may occur to rare plants or habitats from activities that result from the various alternatives. Rare plant species included in the analysis are those that are either listed under the Endangered Species Act, are species of concern, or are on the U.S. Forest Service Northern Region Forester's sensitive species list. The range of a species may extend beyond the Nez Perce-Clearwater; however, the lands administered by the Nez Perce-Clearwater represent the area where changes may occur to these species or their habitats from activities that might be allowed under the alternatives.

Temporal Scale

The temporal scope of the analysis is the anticipated life of the plan.

Past, Present, and Future Activities used in the Analysis

Due to the highly diverse habitats at-risk plant species occupy, the list of activities that may cause threats and stressors to affect plants is extensive and varies by species guild. Generally, timber management, hydrologic changes, grazing, and indirect effects of weed invasion and treatment are often the most important to one or more guilds. A review of the effects of various activities, as well as general and specific plan components, are reviewed in this report. These effects are largely responsible for creating the existing condition for these species and will continue to be the primary agents affecting them into the future. Additional or increasing effects will occur as growing human populations increase forest uses and demands for resources. Climate change will also act to alter forest vegetation and potentially the response of ecosystems and species dependent upon them to activities. Also, potential changes in species status may occur, such as the recent listing of whitebark pine and the delisting of water howellia.

Methods and Assumptions

The indicators were measured by a review of threats and stressors discussed at the species guild level. In this analysis, at risk plant species are grouped into guilds based upon the habitats they occur in. The effects included known factors, potential factors and effects associated with other resource areas and plan components. The number of species and occurrences of species is quantified through general land use categories that are loosely based upon management area designation. These are altered slightly to create general disturbance categories with similar relative threats for alternative comparison.

The first category for comparison is the undeveloped and most protected areas that consist of designated Wilderness Areas, recommended Wilderness Areas, National Historic Landmarks, Research Natural Areas and designated Wild and Scenic Rivers. This area is similar to Management Area 1, but with the addition of recommended wilderness and Research Natural Areas.

The second category is the less protected Inventoried Roadless Areas and suitable Wild and Scenic River in Management Area 2, minus recommended wilderness or research natural areas, which were added to the most protected category because of similarity of effects. Management of these areas may occur subject to appropriate resource measures and regulations that are consistent with these designations.

The third category for comparison is Management Area 3, which has a multiple-use emphasis and includes all lands suitable for timber production.

A summary discussion comparing these measures across the alternatives is provided with effects determinations for species reviewed.

Measurement Indicators

The indicator for analysis is the potential for adverse effects on rare plant species from ground-disturbing activities or other applicable threats or stressors. A quantitative indicator compares the number of at-risk species and occurrences of those species in general threat categories across the alternatives.

Affected Environment

Existing Condition

Table 91 summarizes the status of 51 species reviewed in this analysis. There are three federally listed species; 41 plant species on the U.S. Forest Service Northern Region sensitive species list and 30 species of conservation concern. The latter two groups share several species in common. The analysis also uses habitat guilds that allow for efficient discussion of species occurring in similar habitats. Status changes during the forest planning process include the removal of water howellia from threatened status (U.S. Department of the Interior 2021b) and change of whitebark pine from candidate (and consequent removal from the Sensitive Species list) to proposed for listing (U.S. Department of the Interior 2020b) and finally listing as threatened effective in January 2023 (U.S. Department of the Interior 2021b).

Federally Listed At-Risk Plant Species

Species federally listed as threatened or endangered, proposed, and candidate are listed by the U.S. Fish and Wildlife Service. Under provisions of the Endangered Species Act of 1973, federal agencies are directed to conserve endangered and threatened species and to ensure that actions authorized, funded, or carried out by these agencies are not likely to jeopardize the continued existence of threatened or endangered species, or result in the destruction or adverse modification of their critical habitats. These species are automatically considered "at-risk" species under the 2012 Planning Rule.

Two federally listed species, Spalding's catchfly and whitebark pine are known to occur on the Nez Perce-Clearwater National Forest. One additional threatened plant species, Macfarlane's four o'clock, is included in project level analysis for some parts of the Nez Perce-Clearwater following direction from the U.S. Fish and Wildlife Service that is based upon species distribution and occurrence of nearby habitats; however, despite the presence of populations very close to the Forest boundary, the species has not been found on lands administered by the Forest.

Table 91. Federally listed U.S. Forest Service Northern Region sensitive species and species of conservation concern in the plan area

Species	Federal Status	Global/State Status	RFSS Status	SCC Status	Habitat	Guild
Asplenium trichomanes Maidenhair spleenwort		G5/S1	●	●	Moist, rocky, cliff crevices, and outcrops; humid mesic forests on the Nez Perce-Clearwater.	Rocky
Astragalus paysonii Payson's milkvetch		G3/S3	●		Openings, gaps and transitional habitats in early-mid-seral mixed conifer forests; generally, in areas of grand fir potential vegetation.	Transitional
Blechnum spicant Deerfern		G5/S3	●	●	Shaded understory of mid-to-late-seral western redcedar. Often associated with riparian areas.	Mesic Forest
Botrychium crenulatum Crenulate moonwort		G4/S1	●		Shaded moist sites; generally, under mature western redcedar or meadows.	Mesic Forest
Botrychium lanceolatum var. lanceolatum Lance-leaf moonwort		G5T4/S3	●	●	Shaded moist sites, generally under mature western redcedar or meadows.	Mesic Forest
Botrychium lineare Linear-leaf moonwort		G3/SH	●		Shaded moist sites under aspen or various conifers; dry to moist meadows.	Mesic Forests Meadows
Botrychium minganense Mingan moonwort		G5/S3	●	●	Shaded moist sites, generally, under mature western redcedar, but occasionally other conifers or meadows.	Mesic Forest

Species	Federal Status	Global/State Status	RFSS Status	SCC Status	Habitat	Guild
Botrychium montanum Mountain moonwort		G3/S2	●	●	Shaded, moist sites; generally, under mature western redcedar.	Mesic Forest
Botrychium pinnatum Northern moonwort		G5/S2	●	●	Dry to moist meadows and transitional habitats. Sometimes shaded under moist conifers.	Mesic Forest Meadows
Botrychium simplex Least moonwort		G5/S2	●	●	Dry to moist meadows and transitional habitats. Sometimes shaded moist.	Mesic Forest Meadows
Buxbaumia aphylla Leafless bug-on-a-stick		G5/S1	●		Moist, acidic soils in upper montane to alpine zones. Often mountain parklands.	Grassland Subalpine Forest
Buxbaumia viridis Green bug-on-a-stick		G4G5/S3	●		On large decaying logs or ash soils in moist, late successional grand fir or western redcedar forests. Some affinity for shaded riparian areas.	Mesic Forests
Calochortus nitidus Broadfruit mariposa		G3/S3	●	●	Intact bluebunch/Idaho fescue grasslands or open pine with good seasonal moisture and soil development over basalt	Grasslands
Cardamine constancei Constance's bittercress		G3S3	●		Breaklands and stream terraces, in warm, humid environments of low-elevation canyons; partial shade or transitional habitats.	Mesic Forests Transitional
Carex buxbaumii Buxbaum's sedge		G5/S3	●		Fens, seeps and areas of moisture collection on saturated organic soils associated with broad,	Wetland Meadow

Waldsteinia idahoensis Idaho barren strawberry		G3/S3	●		Transitional habitats and open forests of moist/cool grand fir, subalpine fir and western redcedar forest habitats.	Transitional

T=Federally listed as Threatened. RFSS=Regional Forester Sensitive Species. SCC= Species of Conservation Concern.

Macfarlane's Four o'clock (*Mirabilis macfarlanei*)

MacFarlane's four o'clock is a long-lived, deep-rooted perennial forb in the family Nyctaginaceae. It was federally listed as endangered by the U.S. Fish and Wildlife Service in 1979 (44 Federal Register [FR] 61912) (U.S. Department of the Interior 1979) and down listed to threatened in March 1996 (61 FR 10693) (U.S. Department of the Interior 1996). A revised recovery plan for MacFarlane's four-o'clock was completed in 2000 (U.S. Department of the Interior 2000c). The objective of the recovery program is to delist and remove *Mirabilis macfarlanei* from threatened status by protecting and maintaining reproducing, self-sustaining populations in each of three distinct geographic areas along the Snake, Salmon, and Imnaha river canyons.

Habitat

Per the species account for Macfarlane's four-o'clock produced by Natureserve (2021), habitats supporting MacFarlane's four o'clock are characterized by bunchgrass communities in sandy or rocky soils, typically located on steep slopes with southwestern to western aspects MacFarlane's four o'clock occurs in river canyon habitats in sandy to rocky soils. Talus rock often underlies the soils, and several sites are unstable and prone to erosion. The climate is characterized by warm and dry conditions and most precipitation occurs during winter and spring rains. Plants are most commonly found on steep slopes with southwest to western aspects, although they may be found at any aspect or slope position. MacFarlane's four o'clock typically occurs in bunchgrass communities dominated by bluebunch wheatgrass (*Pseudoroegnaria spicata*). Other native graminoid associates include sand dropseed (*Sporobolus cryptandrus*), red threeawn (*Aristida longiseta*), Sandberg bluegrass (*Poa secunda*), needle and thread (Hesperostipa comata), annual fescue (*Festuca* spp.), and Idaho fescue (*Festuca idahoensis*). Common native shrub and tree associates include gray rabbitbrush (*Chrysothamnus nauseosus*), netleaf hackberry (*Celtis reticulata*), smooth sumac (*Rhus glabra*), and spiny greasebush (*Glossopetalon nevadense*).

Occurrence

MacFarlane's four o'clock is narrowly endemic to portions of the Snake, Salmon, and Imnaha river canyons in northeastern Oregon and adjacent west-central Idaho. The species global range is approximately 46 by 29 kilometers. In the U.S. Forest Service Northern Region, the species has not been found on National Forest System land; however, occurrences are close to potentially suitable habitat on the Nez Perce-Clearwater. On the Nez Perce-Clearwater, apparently suitable habitat occurs in the Rapid River and White Bird Creek basins, as well as along the main Salmon River; however, most of these closely adjacent areas appear to be outside the currently known small range for the species.

Threats

The Heritage Program Network has ranked this species as G2 or Imperiled. Such species are at high risk of extinction or elimination due to restricted range, few populations or occurrences, steep declines, severe threats, or other factors (Young et al. 2015). In Idaho, the Natural Heritage Program has ranked the species as S2 or Imperiled. Such species are at high risk of extirpation in the jurisdiction due to restricted range, few populations or occurrences, steep declines, severe threats, or other factors.

Non-native plant species and uncharacteristically large or frequent wildfires are likely the greatest threats to MacFarlane's four o'clock (U.S. Department of the Interior 2000c). The deep, thick roots of MacFarlane's four o'clock can probably survive most fires, especially because wildfires generally occur later in the summer when the plant is dormant. However, the subsequent increases in non-native plant species associated with these fires may compete for resources. Herbicide and pesticide spraying, landslides and flood damage, and road and trail construction and maintenance are also threats to MacFarlane's four o'clock, especially to one occurrence adjacent to a major highway. Livestock grazing and trampling may indirectly affect MacFarlane's four o'clock through soil erosion, soil compaction, nonnative plant species introduction and seed establishment, and forage selection and avoidance that could alter community composition. Insect damage and disease, wildlife grazing and trampling, recreation such as hiking, off-highway vehicle use, plant collecting, mining, pollinator competition with other species, and inbreeding depression are additional threats that may potentially occur or have been documented (U.S. Department of the Interior 2000c, Kaye 1995).

Trends

This species reproduces sexually by seed and asexually through long spreading rhizomes (U.S. Department of the Interior 2000c). Individuals may comprise several hundred stems ranging up to approximately nine square meters, making it difficult to ascertain changes in the number of plants at a given site (Kaye 1995, Callihan and Lass 1988). In one demographic study, Kaye (1995) found that the number of plants remained relatively stable over a five-year time period at occurrences in the Hells Canyon area. Clonal spread may contribute more to population stability compared to seedling recruitment (Barnes et al. 1997, Kaye 1995), although both are important to long-term genetic stability (U.S. Department of the Interior 2000c). Some studies have found low rates of seedling recruitment (Kaye 1995, Kaye et al. 1990), while others have found that seedling recruitment is a rare event (Barnes et al. 1997, U.S. Department of the Interior 2000c, Johnson 1995, Barnes and Wolf 1994). While existing plants appear to be equipped for longevity, the general habitat degradation that is common at many sites may hinder the establishment of new recruitment, which could hinder species viability in the long term.

Spalding's Catchfly

Spalding's catchfly is a perennial herb in the family Caryophyllaceae. It was listed as threatened under the Endangered Species Act by the U.S. Fish and Wildlife Service in 2001 (U.S. Department of the Interior 2001). While the U.S. Fish and Wildlife Service intends to identify critical habitat for this species, critical habitat designation was precluded at the time of listing due to a lack of funding. The recovery plan for Spalding's catchfly was completed in 2007 (U.S. Department of the Interior 2007) and outlines the recovery strategy, recovery goals, objectives, and delisting criteria. The objective of the recovery program is to recover Spalding's catchfly by protecting and maintaining reproducing, self-sustaining populations in each of the five distinct physiographic regions where it resides, with the ultimate goal of delisting the species.

Habitat

In general, Spalding's catchfly is found in open, vernally moist, mesic grassland communities or sagebrush-steppe communities. The bunchgrass grasslands where Spalding's catchfly primarily occurs are characterized by either Idaho fescue or Idaho fescue with bluebunch wheatgrass except in Montana where the dominant bunchgrass is rough fescue. A Junegrass component is also a good indicator of suitable habitat. The plant is found at elevations ranging from 1,200 to 5,300 feet (U.S. Department of the Interior 2007), usually in deep, productive loess or loamy soils. Plants are generally found on northwest to northeast facing slopes or swales or other landscape features where soil moisture is relatively higher (Hill and Gray 2004). Soils in the Idaho, Oregon, and Washington tristate area are loess wind-dispersed and influenced by ash from volcanic eruptions (Tisdale 1986, Johnson and Simon 1987) Soils in Montana are more glacially influenced (Schassberger 1988). These mesic sites are highly productive, with total plant cover and forage dry weight sometimes three times greater than drier, more shallowly soiled bluebunch wheatgrass communities (Johnson and Simon 1987). Spalding's catchfly is found on a wide range of slopes from flat areas to slopes as great as seventy percent. Most occurrences are found on grades ranging from 20 percent to 40 percent slope (Hill and Gray 2004), although this may be an artifact of where intact habitat has not been converted to other uses.

On the Nez Perce-Clearwater, the species occurs in the canyon grasslands Physiographic Province. Of the five provinces in which the species occurs, this is the most intact; largely because the canyon walls are steep and do not lend themselves to agricultural or urban developments. On the Nez Perce-Clearwater, the typical elevations and aspects do not generally support grasslands. At these higher elevations of 4,000 to 5,000 feet in the canyon grasslands, the northern slopes are inhabited by tree species and Spalding's catchfly is found on gentle southern slopes where the appropriate bunchgrass communities reside. Because of inaccessibility and steep topography, the Canyon Grasslands are the most under surveyed area for Spalding's catchfly and also represent the area where large populations of Spalding's catchfly may be most easily conserved because they are more removed from human influence.

Occurrence

According to the U.S. Fish and Wildlife Service five-year review results, Spalding's catchfly is currently known from 139 populations across its range in Montana, Idaho, Oregon, Washington, and British Columbia, with 49 being in Idaho (U.S. Department of the Interior 2020a), where it's limited to canyon grasslands with a few on the Palouse Prairie of the west central portion of the state. Populations are often small and isolated with relatively few holding the majority of the range wide population. There are three occurrences on lands administered by the Nez Perce-Clearwater. A range wide study by Lesica (2016) found the occurrences on the Nez Perce-Clearwater to be genetically unique from all other occurrences.

Threats

Listing documents for Spalding's catchfly catalogs seven management activities that potentially threaten habitat or populations. They are grazing, recreation, fire use, exotic species, pollinator impacts, herbicide and pesticide use, and habitat conversion.

Spalding's catchfly is impacted by habitat loss due to human development, habitat degradation associated with adverse grazing and trampling by domestic livestock and wildlife, and invasions of aggressive nonnative plants. In addition, a loss of genetic fitness, defined as the loss of genetic variability and effects of inbreeding, is a problem for many small, fragmented populations where genetic exchange is limited. Other impacts include changes in fire frequency and seasonality, prolonged drought, insect damage and disease, off-road vehicle use, and herbicide spraying and drift. In Idaho, Hill and Gray (2005) found that rodent activity appeared to be related to the mortality of Spalding's catchfly plants. In Montana, Lesica (1999) found that fire did not appear to affect recruits or adults in some years, but Hill and Gray (2005) observed that it may indirectly affect Spalding's catchfly by increasing introduced weed species. Other observations seem to indicate some disturbances, such as grazing or fire, may be important to the long-term persistence of this species in northwest Montana as a result of reduced competition with the larger, litter-producing native bunchgrasses, primarily rough fescue, with which it co-occurs (Lesica 1997). However, bunchgrasses in Idaho do not produce as much litter so this mechanism may not apply.

At the three occurrences on the Nez Perce-Clearwater, grazing occurs, but, although some effects have been noted, this use generally does not appear to be a major impact due to the managed livestock movements in relation to population locations, fencing, and low stocking levels in the allotments involved. Wildlife grazing and rodent activity have been observed but at very low levels. The greatest threat to the species on the unit appears to be weeds and general habitat degradation.

Trends

Populations of Spalding's catchfly have been extirpated in some portions of its range ad are stable in others, depending on the particular threat to each population(U.S. Department of the Interior 2007). Due to species biology and life history, populations may vary in number from year to year. Periodic dormancy, likely due to species biology and climatic conditions, is common and can result in fluctuating population counts over time. As directed by the recovery plan, range wide monitoring of the species' key conservation areas will measure trends that will guide management of the species status. Monitoring methods concerning timing and frequency of measurement are designed to account for the annual variations in population counts.

Whitebark Pine (*Pinus albicaulis*)

On July 19, 2011, the U.S. Fish and Wildlife Service published in the Federal Register (U.S. Department of the Interior 2011b) its 12-month status review finding on a petition to list whitebark pine (*Pinus albicaulis*) under the Endangered Species Act. After a review of all available scientific and commercial information, the U.S. Fish and Wildlife Service concluded that listing the species as threatened or endangered is warranted but precluded by higher priority actions. This made the species a candidate for federal listing as threatened or endangered. Following this action, the U.S. Forest Service Northern Region added whitebark pine to its sensitive species list in 2011. On December 2, 2020, the Fish and Wildlife Service published a proposed rule to list the whitebark pine as a threatened species under the Act. Following this designation, the species was included with federally listed species as part of a biological assessment and no longer treated as a sensitive species by the Forest Service. On December 15, 2022, the Service listed the whitebark pine (*Pinus albicaulis*) as threatened under the Endangered Species Act (U.S. Department of the Interior 2022b). This listing rule went into effect on January 17, 2023.

Habitat

Whitebark pine forests occur in two high mountain biophysical settings. Most common are upper subalpine sites where whitebark pine is the major seral species that is always replaced by the shade-tolerant subalpine fir (*Abies lasiocarpa*), Engelmann spruce (*Picea engelmannii*), or mountain hemlock (*Tsuga mertensiana*), depending on geographic region (Arno and Weaver 1990). These sites support upright, closed-canopy forests and occur on favorable positions in the upper subalpine transitioning to timberline down to above or overlapping with the elevational limit of lodgepole pine (Pfister 1977, Arno and Hoff 1990). On the Nez Perce-Clearwater, most whitebark pine probably occurs in this situation.

On sites where whitebark pine is the only tree species able to successfully dominate, high elevation settings are found at particularly harsh sites in the upper subalpine and at treeline on relatively dry, cold slopes where trees often occur in elfin forests, clusters, groves or tree islands (Arno and Hoff 1990, Arno 1986, Steele et al. 1983). Other species, such subalpine fir, Engelmann spruce, and lodgepole pine (Pinus contorta), can occur on these sites, but they occur as scattered individuals with truncated growth forms and they never dominate a stand (Arno and Hoff 1990, Cooper et al. 1991, Pfister 1977). Whitebark pine can also exist as krummholz in the alpine treeline ecotone (Arno and Hoff 1990)and as a minor seral in lower subalpine sites (Cooper et al. 1991, Pfister 1977).

Occurrence

The distribution of whitebark pine includes coastal and Rocky Mountain ranges that are connected by scattered populations in northeastern Washington and southeastern British Columbia. Occurrences are found in scattered areas of the warm, dry Great Basin but whitebark pine typically occurs on cold, windy high-elevation or high-latitude sites in western North America. As a result, many stands are geographically isolated (Arno and Hoff 1989, Keane and Parsons 2010). Extensive forests form in the Northern Rocky Mountains of the United States and it is also abundant on the eastern slope of the Cascades and Coastal Ranges; however, whitebark pine assumes a patchier distribution at the northern end of its distribution in the Canadian Rockies and Coast Ranges of British Columbia (Arno and Hoff 1990). More than 90 percent of whitebark pine forests exist on public lands, including those managed by the Forest Service and the National Park Service in the United States and by provincial and federal agencies in Canada (Keane et al. 2012).

On the Nez Perce-Clearwater, substantial whitebark pine forests occur in the high Bitterroots in the eastern portion of the unit, in the Gospel Hump Wilderness, the west boundary of the Slate Creek basin, and in the Seven Devils to the southwest. Other occurrences are in the Selway Crags, the Williams Range, and on the highest points west of the Selway River. Outside of these locations scattered whitebark pine are found in low numbers on only a few of the highest summits.

Threats

There are three primary factors contributing to the decline of whitebark pine, including insect outbreaks, fire management, and introduced disease. There have been several major mountain pine beetle (*Dendroctonus ponderosae*) outbreaks that have killed many cone-bearing whitebark pine trees over 20 centimeters in diameter at breast height (Waring and Six 2005, Arno 1986). Climate change is also expected to play a role in the species decline.

The effects of an extensive and successful fire-exclusion management policy since the 1930s have also reduced the area burned in whitebark pine forests, resulting in a decrease of suitable conditions for whitebark pine regeneration (Keane and Arno 1993, Kendall and Keane 2001). Whitebark pine benefits from fire because it is better adapted to surviving and regenerating after fire than associated shade-tolerant trees (Arno and Hoff 1990). Whitebark pine is slow growing in both height and diameter and it rarely grows faster than most of its competitors except on the most severe sites (Arno and Hoff 1990). It is often eventually replaced, in the absence of fire, mainly by the shade-tolerant subalpine fir but also by Engelmann spruce and mountain hemlock. Lodgepole pine can out-compete whitebark pine during early successional stages in some subalpine forests (Arno et al. 1993, Day 1967, Mattson and Reinhart 1990). Decades of fire suppression have limited the benefits of fire and favored other species.

Finally, the introduction of the exotic fungus white pine blister rust to the western United States circa 1910 has killed many five-needle pine trees, and whitebark pine is one of the most susceptible to the disease (Keane and Arno 1993, Kendall and Keane 2001, Hoff et al. 1980, Murray et al. 1995). The cumulative effects of these three agents have resulted in a rapid decrease in mature whitebark pine over recent decades, especially in the more mesic parts of its range (Keane and Arno 1993).

Predicted changes in the Northern Rocky Mountains due to climate change could further exacerbate whitebark pine decline by increasing the frequency and duration of beetle epidemics, blister rust infections, and severe wildfires (Running 2006, Logan and Powell 2001, Blaustein and Dobson 2006). However, changes in fire regimens may actually favor regeneration of whitebark pine due to its fire adaptations. In addition, such changes may reduce competition with other species. Overall, whitebark pine is not expected to do well under future climates, primarily because of the current threats and severely declined populations, its confinement to upper subalpine environments, and its lack of ability to regenerate because of nutcracker consumption of seed in areas of low whitebark pine populations (Halofsky, Peterson, et al. 2018a, b).

Trends

A severe and steep downward trend has been occurring in the whitebark pine population and health over the past few decades, especially in the Northern Rocky Mountains (Keane et al. 2012). This decline is expected to continue into the foreseeable future, although the rate may lessen simply because there are fewer live trees left to be impacted by disease or other threats. Mortality data collected in multiple studies throughout the range of whitebark pine strongly illustrates this substantial and pervasive decline throughout almost the entire range of the species (Committee on the Status of Endangered Wildlife in Canada 2010).

In Canada, based on current mortality rates, it is anticipated that whitebark pine will decline by 57 percent by 2100 (Committee on the Status of Endangered Wildlife in Canada 2010). The value for this anticipated decline is likely an underestimate, as it assumes current mortality rates remain constant into the foreseeable future while past trends have shown that mortality rates have been increasing over the last several decades. The range of mortality rates for whitebark pine in the United States are similar to those in Canada, which suggests that the anticipated rates of decline will be similar.

The Pacific Decadal Oscillation effects are determined by Northern Pacific surface water temperatures and influence climatic trends across the Northern Rockies and Great Plains. Over the last century, in Montana and Northern Idaho, it is evident that the Pacific Decadal Oscillation influencing the western regional climate including the U.S. Forest Service Northern Region area has also influenced disturbances such as fire and mountain pine beetle and contributed to the ongoing whitebark pine decline. Given that the probability of continuing disturbance is high as climate projections predict a warming trend, the mortality of seed-producing whitebark pine may also be high.

There is substantial concern over the ability of whitebark pine to sustain itself throughout its range through natural regeneration. Some natural selection for resistance to blister rust is likely occurring (Hoff et al. 2001) but recovery will be slow as the species is slow growing and needs 60 to 80 years to produce sizable cone crops. The regeneration of the species is further hindered by evidence suggesting that stands with low basal area of live whitebark pine will not reliably attract nutcrackers to support seed dispersal (McKinney et al. 2009). Reduced populations also face risks of inbreeding depression that may result in slow growth and less hardy trees that often exhibit lethal genes.

The extensive studies of whitebark decline, along with decades of experience and observation, substantiates the past and ongoing severe decline of the species throughout its range, including the planning area and the expectation that this decline will continue for some time into the future. There is an urgent need to focus on conservation and restoration efforts for this keystone species across the extent of its range (Keane et al. 2012).

Projects are being implemented across the National Forests of U.S. Forest Service Northern Region and plan components in revised plans seek to slow or reverse the declining trend of this species.

Species of Conservation Concern

Under the 2012 Planning Rule, in addition to federally listed species, plant species at-risk on the Nez Perce-Clearwater includes species of conservation concern designated by the Regional Forester of the U.S. Forest Service Northern Region where best available scientific information indicates substantial concern about the species' capability to persist over the long-term in the plan area (36 CFR §219.9; Forest Service Handbook [FSH] 1909.12 Ch. 10, Part 12.52).

The process for identifying these species and the designated species of conservation concern for the Forest are outlined on the U.S. Forest Service Northern Region species of conservation concern (https://www.fs.usda.gov/detail/r1/landmanagement/planning/?cid=fseprd500402). State conservation rankings, along with the other criteria in FSH 1909.12 Chapter 10 Section 12.52 and Chapter 20 Section 21.22, were used to develop the Regional Forester's at-risk plant species for the Forest. Using data from Nature Serve, the Idaho Natural Heritage Program, the current Regional Forester sensitive species list, along with input from other agencies and knowledgeable individuals, 92 potential species of concern for the Forest were compiled for initial assessment. Of these, seven were determined not to be documented on the Nez Perce-Clearwater, leaving 85 for closer evaluation. Thirty species were determined by the Regional Forester to currently be plant species of conservation concern on the Forest.

The final plant species of conservation concern list will replace the sensitive plant species list for the Nez Forest under the action alternatives. The identification of species of conservation concern is dynamic and may change over time, as has the Regional Forester sensitive species list.

Habitat Guilds

Plant species are grouped in guilds for purposes of analysis based on broad similarity of the habitats they occupy. Each guild may contain a varied collection of specific habitats and the potential response to a species to threats. Associated conservation strategies for species in the guild would generally be very similar, allowing for more efficient analysis and identification of relevant information pertaining to the species. Threats and stressors are included in this affected environment discussion because they have shaped the present existing condition for these species. Some species may occur in more than one guild. Rare plants on the Nez Perce-Clearwater are grouped in the following guilds.

Grasslands Guild

This habitat grouping contains 11 species evaluated in this environmental impact statement. Two are currently designated as threatened by the U.S. Fish and Wildlife Service; six are on the Regional Forester sensitive species list; and seven will be species of conservation concern under the 2012 Planning Rule.

Habitats included in this guild are primarily canyon grasslands that include both warm and cool bunchgrass communities. Due to similarity in community composition, it also includes open pine savannas and areas of potential pine encroachment of drier forest communities. In cooler situations with gentler terrain and moisture retention, prairies may form. In lower-elevation, drained, rocky soils xeric species may dominate and may include significant shrub components of mountain mahogany, green bush, rabbit-brush, or sage. Montane grasslands may be the result of snow and moisture displacement from winter winds that limit tree growth. These higher-elevation habitats are grouped with the grassland guild but are well separated and support different plant communities. Despite these habitats being fairly unique, none of the components of such higher-elevation grassland plant communities were determined to be at-risk species.

Invasive species represent the primary threat to grassland communities. These habitats are naturally open, relatively warm and dry, and generally with abundant open soils. These factors combine to give such sites a high risk of weed infestation. Currently, weeds displace desirable native species in grassland habitats over a substantial area of the Nez Perce-Clearwater. Grazing by both livestock and wildlife can help maintain grasslands in some instances but both can result in localized harm, alteration of habitats, and soil disturbances readily invaded by weeds. Recreational activities can also degrade these habitats through soil damage and user created trails through sensitive areas. Decades of fire suppression has encouraged the encroachment of trees into grasslands and species conversion has promoted a decline of open pine savannas that are often adjacent to grasslands.

The seven species of conservation concern species in this guild are: broadfruit mariposa, Palouse thistle, Idaho hawksbeard, giant helleborine, Howell’s gumweed, spacious monkeyflower, and plumed clover. The federally listed species in this guild are Spalding’s catchfly and Macfarlane’s four-o’clock; the latter is not known or expected to occur on Forest lands; however due to proximity is required to be addressed in project analysis.

Meadows Guild

This group contains seven species evaluated in this environmental impact statement. Six of these are sensitive species, while five will be species of conservation concern under the 2012 Planning Rule.

This small group includes seasonally moist meadows that are dominated by moist sedge communities that have a broad transition to meadow grasses and forb communities. On the wet end, meadows merge into marshes and sedge flats that support wet or saturated soils most of the year. These sites may be quite moist in spring but are generally quite dry by mid-summer. Due to the broad extremes in moisture content through the growing season, these habitats support an unusually high diversity of plant species. These habitats are limited in area and generally found around the fringe of wetlands or occupy swales in or near the drier forest types.

Any changes to hydrologic function of these habitats may threaten these environments, whether from natural or human-caused sources. Specific activities that could provide a threat to these habitats include soil and vegetation disturbances, such as road construction and maintenance; ditching; livestock use; manipulation of adjacent vegetation either through timber harvest, conversion or fire disturbances or exclusion that change hydrologic regimes; invasive species and the treatments of these species; recreational uses, particularly trampling by foot or vehicle use; and succession of some vegetative communities or encroachment of adjacent vegetation. Climate change may alter stream flows, timing of snowmelt, and other hydrologic factors.

The five species of conservation concern species in this guild are: sweetgrass, least moonwort, northern moonwort, sticky goldenweed, and Douglas clover.

Mesic Forests Guild

There are 19 species evaluated under this group in this environmental impact statement. All 19 are sensitive species and 12 will be designated as species of conservation concern under the 2012 Planning Rule.

This is a broad group that mostly includes mid-to-late successional grand fir, western redcedar, and western hemlock forest communities. There may be cool or relatively warm environments, with the latter hosting a well-developed local, inland maritime climate that supports several coastal disjunct species as well as endemic species.

Species of this habitat guild are favored by mid-to-late seral conditions in the moister forest types. Threats to such habitats are any activity that appreciable alters the light or moisture regimes sufficient to render such sites unsuitable to support representative species. The most common events would be some forms of timber harvest or wildfire. In the long-term, climate change could potentially alter moisture regimes sufficiently to change the forest community. In the shorter term, drought or prolonged periods of increased warmth could change fire regimes. Invasive weeds are generally not a threat in enclosed moist forest, but some species can release and displace native species after opening of the crown by fire, harvest, or wind events.

The 12 species of conservation concern species in this guild include deerfern, lance-leaf moonwort, Mingan moonwort, mountain moonwort, northern moonwort, least moonwort, Pacific dogwood, clustered lady’s-slipper, chickweed monkey-flower, sweet coltsfoot, licorice fern, and Sierra woodfern.

Rocky Habitats Guild

The environmental impact statement evaluates ten species in this grouping; currently six are on the sensitive list, while nine will be species of conservation concern under the 2012 Planning Rule.

Plants of this guild are grouped due to their affinity for rocky surfaces rather than the general vegetative zone or type. Sites may be talus, scree, bedrock, or outcrops that may be moist or dry and might occur in grasslands or forests under a variety of light regimes. Such habitats typically occupy the fringe of other habitats, particularly dry grasslands or forests, but may also be common in wet forests, especially on the northern parts of the Nez Perce-Clearwater. Limited soil development and seasonally dry growing conditions often results in low herbaceous cover. Bryophyte and lichens often dominate some rocky sites.

Threats to these habitats include the mining of rock from outcrops and quarries and road construction. Also, some of these habitats are open and dry and are susceptible to weed invasion and treatment of these weeds may harm non-target species. Land management of any kind that could change the light or moisture regimes of such sites also pose a potential threat. Climate change may also impact these ecological factors and prolonged drought may promote desiccation and vegetative changes.

The nine species of conservation concern species in this guild include maidenhair spleenwort, Idaho hawksbeard, Howell’s gumweed, Salmon-flowered desert parsley, chickweed monkeyflower, spacious monkeyflower, gold-back fern, nail lichen, and Salmon River sedum.

Subalpine Forests Guild

There are three species identified in this habitat guild. All three are sensitive plant species, with one, whitebark pine, now listed as threatened. Under the 2012 Planning Rule there will be one species, Idaho douglasia, listed as a species of conservation concern and the threatened whitebark pine is retained.

This is a broad category that includes cool subalpine forests that may be closed or open and are dominated by subalpine fir and whitebark pine. Such forests may form open parklands that may include montane grasslands, rocky habitats, or higher elevation barrens.

Due to the often-remote locations, these habitats generally have relatively few human threats or stressors, although recreational uses such as trails, camping, and wheeled vehicle use may occur in small areas. Changes in fire patterns and severity and associated effects on vegetation may be a stressor in some environments. Such changes may be related to climate change or fire exclusion or suppression. Increased temperatures and prolonged summer drought conditions may increase the risk of desiccation. Motorized winter recreation can be a threat where this use occurs in whitebark pine habitat. Where trees are accessible, snowmobiles may run over the leader or upper portions of the tree that protrude above the snow and cause physical damage.

Transitional Habitats Guild

This analysis includes six species in this group. All six are sensitive specie; two of which will be a species of conservation concern under the 2012 Planning Rule.

This guild contains species that frequent sites that are transitional ecologically such as occurs with canopy gaps, shrublands, edges, or ruderal and disturbed sites. Most inhabited areas have a site potential of forested habitats, and the species may have low occurrence in mature forest. These species are grouped separately because they are best represented and set apart from general forest species by a high affinity for early-seral conditions often related to management.

These habitats are generally created or maintained through natural or man-made disturbance. Common activities promoting transitional habitats are timber harvests, creation of road corridors, wild and prescribed fire, and recreational development or uses. While these activities may harm individuals that prefer such open or edge habitats, the disturbance is generally necessary to maintain or enhance conditions that these species prefer and are generally most prolific under. Weeds that also prefer such conditions may compete with these species in some settings and non-target mortality from treatment of such weeds may also be a threat. Probably the most significant threat to these habitats would be the progression of succession, brought about through fire suppression and declines in vegetation management.

The species of conservation concern species in this guild include Pacific dogwood and Dasynotus.

Wetlands Guild

This habitat guild includes eight plant species analyzed in this environmental impact statement. One is listed as threatened by the U.S. Fish and Wildlife Service. Six are sensitive species; two of which are identified as a species of conservation concern.

This broad guild includes species found in wet sedge meadows, fens, aquatic habitats, and the immediate riparian and shrub swamps. The majority of the species in these communities are obligate wetland species and the sites remain wet most or all of the year. Fen habitats are always groundwater-dependent with accumulating organic matter (Chadde et al. 1998). These wetlands form where high water tables and permanent saturation slows rates of decomposition and where soils are formed from accumulating partially decayed organic matter. They are fed by precipitation, surface water, and ground water and may be mineral rich (alkaline) or poor (acidic) depending upon the surrounding geology. They are dominated by grasses, sedges, and mosses but frequently have a high diversity of other species. These habitats are uncommon. Other habitats in this guild are associated with ponds and river margins where standing water is generally present. Such sites may be riparian, marshes, or swamps with a shrub or tree component that may be seasonally flooded. Vegetation here is generally emergent and rooted in mineral soil.

Threats and stressors to these environments would be similar to those of the meadow habitat guild. However, while those moist habitats transition into relatively dry sites throughout the season, wetlands remain wet all or most of the year and may be more impacted by hydrologic alterations, such as floods or severe drought. While weed infestations are possible, they are less of a problem on the Nez Perce-Clearwater where few aquatic invasive species are found.

The species of conservation concern species in this guild include crested shield-fern and giant helleborine.

Environmental Consequences

The effects analysis includes summaries of management direction for the alternatives, as well as general effects common to the alternatives. The alternative comparison focuses on the number of species with status. For the botany analysis, Forest is divided into three categories based upon general grouping of potential effects. These categories are described in the discussion of the No Action Alternative below. The number of species and occurrences in each category are provided for each alternative. The list of species found in each category is generally long and similar across the alternatives, so they are not provided in this analysis. Federally listed species are included in discussion of the category where they occur.

Effects Common to All Alternatives

The Affected Environment includes the discussion of the species habitat groupings or guilds discussed in this analysis. The general threats and stressors to these guilds are included in that section because these natural or man-made influences have contributed to the status and existing condition of these elements. The effects of these disturbance agents are accounted for in the following discussion. In the effect's discussion, guilds are mentioned when pertinent. The comparison across alternatives focuses on a quantitative presentation of the number of species and occurrences present in general threat categories that are somewhat based upon management areas.

Sensitive or at-risk plant species occupying habitats that are often disturbed, such as roadsides, suitable timberlands, and high recreation use areas, would be prone to removal of suitable habitat, as well as direct removal of individuals, although some sensitive or at-risk plant species can respond favorably to these disturbances. Various surface-disturbing activities, including mineral exploration, development, and the associated roads, rights-of-way, and corridors, can directly affect habitats for sensitive or at-risk plant species. Recreational use, collection of plants, fire, as well as improper livestock grazing, could remove or trample vegetation and disturb soil, resulting in adverse impacts to sensitive or at-risk plant species.

Surface-disturbing activities also can indirectly affect sensitive or at-risk plant species by contributing to soil erosion and transporting invasive species into at-risk plant species habitats. The spread of invasive species could adversely affect sensitive or at-risk plants due to the limited population size and distribution of these rare plants. Surface disturbance also can result in habitat fragmentation, which can isolate populations of sensitive or at-risk plant species. Populations of sensitive or at-risk plant species often have a patchy distribution across the landscape and eliminating one or more populations can prevent gene flow among populations if residual populations are too far apart for sufficient cross-pollination. Habitat fragmentation would be a long-term impact to sensitive or at-risk plant species. Utilizing plan components and mitigating projects to minimize surface disturbing and disruptive activities minimizes adverse impacts from surface disturbance across all alternatives.

Habitats that are less subjected to land management activities, such as inaccessible areas, rugged terrain, rocky habitats, and wetlands, are more likely to be intact. There are fewer management threats to these species and the anticipated adverse impacts from surface-disturbing activities are minimal. The main threats to these areas include invasive species and climate change or in some guilds the increase uncontrolled wildfire that result in the loss of forest in a later stage of succession. In the past, roads were built along waterways and through wetlands. There are protections for these habitats in all alternatives, yet some roads are still on the landscape in those areas and may still be affecting those habitats. Management actions that restrict surface disturbance on unstable slopes would result in beneficial impacts to the species involved.

As these habitats are altered, species adapted to restricted habitats or specific microclimates would have lower survival rates than the more common native species with wider amplitude of habitats. Threats to these habitats include direct disturbance, such as from logging equipment, road building, road maintenance, grazing, and fire suppression activities; habitat alteration, such as canopy removal, edge effects from roads, herbicide, and fire exclusion; climate change; and invasive species.

Climate controls many ecosystem processes including species distribution and abundance, regeneration, vegetation productivity and growth, and disturbance, all of which could affect at-risk species on the Nez Perce-Clearwater National Forest. While there is some uncertainty regarding the scale, rate, and direction of future climatic conditions, the majority of published science suggests that warming trends may strongly influence the frequency, intensity, and size of disturbances, such as fire and extensive insect outbreaks, in coming decades. Changes in disturbance prompted by climate change are likely as important as incremental changes in temperature and precipitation for affecting ecosystem productivity and species composition. Recent research indicates that these risks may be particularly acute for forests of the Northern Rockies. Conservative future climate scenario models predict that the effects of warming trends result in a lengthened growing season, decreased number of days with snow on the ground, earlier peak snow occurrence, and increased water stress for all sites in the study which represent the temperature and precipitation spectrum in the forests of the Rocky Mountain region (Boisvenue and Running 2010). Mountain ecosystems are likely to shift upslope, reducing habitat for many subalpine and alpine tundra species. Mountain treeline is predicted to rise by roughly 350 feet for every degree Fahrenheit of warming (U.S. Environmental Protection Agency 1997).

All habitat guilds for at-risk species are expected to be impacted by warming trends. Aquatic, wetland-riparian, grasslands, and shrublands may increase the rate of desiccation due to increased and prolonged summer temperatures and drought conditions, although, due to uncertainty, the opposite could be true, and all guilds could see an increase in precipitation along with increased temperatures. Habitat in the subalpine habitat guild for at-risk plant species may decrease as a result of climate change and an upward shift of lower alpine habitats. Increased fire severity or frequency may also affect all habitats in all guilds, especially those found outside of rocky and aquatic areas, and this may affect the associated at-risk plant species either favorably or detrimentally depending on the habitat requirements for each species.

Increases in the severity of disturbances, combined with projected warming trends, may limit habitat for at-risk species. Rare and uncommon species, disjunct populations, and species at the edge of their known range are expected to experience a number of barriers when adjusting to warming trends because of the combination of a small number of occurrences, narrow elevation ranges, and requirements of specific soils types. Some at-risk species with potential habitat within the project area are known to occur on restricted and/or limited areas on the Nez Perce-Clearwater. Plants confined to outcrops of special soils are generally expected to have a far lower chance of successful migration to new suitable sites and far greater risks of extinction in the face of climate change than plants that are soil generalists (Harrison et al. 2009). Because of the uncertainty in scale, direction, and rate of climate change, management of at-risk plant species on the Nez Perce-Clearwater focuses on maintaining viable populations throughout the species known range on the Nez Perce-Clearwater to ensure persistence.

Effects of the No Action Alternative

Management Direction under the No Action Alternative

The 1987 Clearwater and Nez Perce Forest Plans provide management guidance to natural resource managers within the framework of Congressional intent (36 CFR 217). Page II-2 of the Clearwater Forest Plan provides general management direction that directs management to "manage habitat to contribute to recovery of each threatened and endangered species occurring on the Forest." Amendment 3 of the Nez Perce Forest Plan Page II-1 directs management to "provide habitat to contribute to the recovery of threatened and endangered plant and animal species in accordance with approved recovery plans. Provide habitat to ensure the viability of those species identified as sensitive." The current forest plans do not contain specific standards or guidelines related to any federally listed or sensitive plant species.

Neither of the 1987 plans indicates the presence of any federally listed plant species occurring on either forest at that time. Since that time, plants listed as federally threatened or as a proposed for listing have been determined to be present on the combined Nez Perce-Clearwater National Forest. In addition, one species federally listed as threatened occurs very near the Forest boundary and must be addressed in project analysis as directed by the U.S. Fish and Wildlife Service. The combination of the Forest Service manual policy for Regional Forester's sensitive plant species and the existing two plans provide protections that are similar to revised plan components in that the plans and direction would ensure that at-risk species persist on the Forest. However, the existing plans have fewer opportunities for restoration and less of a focus on native vegetation improvements than provided by the new plan components; therefore, under the No Action Alternative, the possibilities for improving habitat conditions for at-risk plant species are reduced.

Effects of the No Action Alternative

Population viability is expected to remain stable for all sensitive species on the Forest with current management policies and direction of the 1987 forest plans. Habitat quality has the potential to improve; however, there are fewer plan components promoting restoration. The No Action Alternative is expected to maintain similar habitat quality for sensitive plant species in all habitat guilds. Threats would remain similar to current conditions for sensitive plants. While the No Action Alternative will retain management areas of the existing plans, the management areas of the action alternatives, altered to similar threat categories for the botany resource analysis, are used as the basis of comparison for all alternatives.

Undeveloped and most protected areas are provided by designated Wilderness Areas, recommended Wilderness Areas, National Historic Landmarks, designated Wild and Scenic Rivers, and Research Natural Areas. This area is Management Area 1 but with the addition of recommended wilderness and Research Natural Areas. Less protected roadless areas include suitable Wild and Scenic Rivers and designated Inventoried Roadless Areas that are not recommended wilderness. This category is Management Area 2 without the recommended wilderness or research natural areas, which are more protected. Management of these areas may occur subject to appropriate resource measures and regulations that are consistent with these designations. The third area includes areas for timber production and multiple uses. This category is the same as Management Area 3 with no changes other than the removal of research natural areas. Generally, the emphasis on timber production in these areas increases threats from habitat manipulation for most rare plant species. These three disturbance groupings are summarized in the following table. The analysis quantifies all known occurrences for each species that are within these relative categories to provide a general comparison of protection and effects.

Table 92. Protection categories for botanical analysis

Most Protected	Less Protected	Timber Production
Designated Wilderness Recommended Wilderness National Historic Landmarks Research Natural Areas Designated Wild and Scenic Rivers	Designated Roadless Areas (with the removal of recommended wilderness and proposed research natural areas) Suitable Wild and Scenic Rivers	Management Area 3 (with the removal of research natural areas)

The most protected areas include approximately 1,449,984 acres, or 37 percent, of the national forest under the No Action Alternative. The federally listed Spalding's catchfly occurs at one location in these more protected areas that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. Within this area, 30 reviewed plant species with 165 known occurrences are found. The No Action Alternative still considers Regional Forester's sensitive plant species. Of the 30 plant species reviewed, 28 are currently included on the sensitive species list. Two species are not sensitive species and would not be included as a species of any status under this alternative; however, they would be designated as a species of concern under the other alternatives. Under this alternative there are 12 sensitive species consisting of 67 occurrences in this category that will not carry forward as a species of conservation concern under the other alternatives.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include more quality habitat in all habitat guilds. The No Action Alternative offers less of the most protected category than Alternative W, Alternative Z, Alternative Y, and the preferred alternative but more than Alternative X. While alternatives with higher acreage in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

The less protected areas comprise approximately 1,279,389 acres, or 32 percent, of the Nez Perce-Clearwater under the No Action Alternative. Whitebark pine occurs in all montane areas. Within this area 26 reviewed plant species with 182 known occurrences are found. The No Action Alternative still considers Regional Forester's sensitive plant species. Of the 26 plant species reviewed, 25 are currently included on the sensitive species list. One species is not a sensitive species and would not be included as a species of any status under this alternative. It would be designated as a species of concern under the other alternatives. Under this alternative, there are 10 sensitive species consisting of 95 occurrences in this area category that will not carry forward as a species of conservation concern under the other alternatives.

Due to reduced ground disturbance and weed spread vector potentially offered by more restricted management, these areas include quality habitat in all habitat guilds. The No Action Alternative offers less roadless area in this category than Alternative X but more than the preferred alternative, Alternative Y, Alternative Z, and Alternative W, in that order. While alternatives with higher acreage in roadless areas of Management Area 2 would allow fewer, more restricted activities that may affect species of concern, there is also a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are 1,209,427 acres, or 31 percent, of the Forest proposed as suitable for timber production under this alternative. This category is the same as Management Area 3. The federally listed Spalding's catchfly occurs at two locations in this management area that is subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine may occur in montane areas that reach suitable elevations, though such areas probably represent only a trace occurrence. Within this management area 35 reviewed plant species with 335 known occurrences are found. The No Action Alternative still considers Regional Forester's sensitive plant species. Of the 35 plant species reviewed in Management Area 3 in this alternative, 29 are currently included on the sensitive species list. Six species are not currently sensitive species and would not be included as a species of any status under this alternative, but these species would be designated as a species of concern under the other alternatives. Under this alternative, there are 11 sensitive species consisting of 142 occurrences in this management area that will not carry forward as a species of conservation concern under the other alternatives.

Due to increased vegetation management in Management Area 3, there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is very similar under all alternatives, with the No Action Alternative being slightly less than the action alternatives. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. The at-risk plant species would be protected by policy and Land Management Plan components during management activities to prevent trends towards listing.

Effects Common to Action Alternatives

Management Direction under Alternatives W, X, Y, Z, and the Preferred Alternative

All action alternatives contain Land Management Plan components that explicitly state the desired conditions for vegetation conditions, livestock grazing, timber harvest, and other resource areas that may involve at-risk species habitats. The components that are likely to have an effect on at-risk plant species habitat guilds are summarized primarily under the resource specific discussions below.

Plan components that are most relevant to at-risk plants are the same for each action alternative. The management direction recognizes the need to maintain or improve occurrences and habitats of at-risk plants. Vegetation components of the revised plan describes the desired conditions and objectives for at-risk plants or habitats, some of which have species-specific components. Management strategies include evaluation of areas proposed for management activities for the presence of occupied or suitable habitat for at-risk species, focusing on increasing known information for these and other botanical elements, and monitoring known occurrences of such species. The specific direction for project level evaluation of species of conservation concern has not yet been finalized by the agency. Federally listed species are evaluated through a biological assessment in consultation with the U.S. Fish and Wildlife Service.

Effects Common to Alternatives W, X, Y, Z, and the Preferred Alternative

As a result of the action alternative plan components, at-risk plant populations in all habitat guilds are expected to be maintained and the associated habitats will continue supporting at-risk plant species with opportunities to restore sites if conditions warrant. Regional Forester's Sensitive Plant Species that are not currently on the proposed species of conservation concern list would no longer be specifically protected once the new plan is implemented. The dropped Regional Forester's Sensitive Plant Species generally occur in habitats with either infrequent project activity or in sensitive habitats protected by Land Management Plan components. If new pertinent information becomes available indicating a potential threat to persistence on the Nez Perce-Clearwater these species would be reconsidered, and the species of conservation concern list may be adjusted.

Populations of plant species of conservation concern are expected to persist in the plan area because the plan components regarding them will maintain and restore habitat for these species. Through proposed plan components habitat quality would improve for whitebark pine under the action alternatives at a faster rate than the No Action Alternative, though both provide benefits and support long term persistence on the Forest. The action alternatives include additional opportunities for restoration activities; however, the No Action Alternative and action alternatives result in similar outcomes for at-risk plants. Habitat quality is expected to improve under the action alternatives at a slightly faster rate for most at-risk plant species than the No Action Alternative due to an increase in restoration projects.

Meeting or moving toward proper functioning conditions across all alternatives improves habitat for at-risk plant species. Effects to at-risk plant species across all habitat guilds would be similar across the action alternatives, with slight differences attributed to acres of management area designation.

Effects that Vary by Action Alternative

Effects of Alternative W

Undeveloped and more protected areas in Alternative W comprise about 2,072,380 acres, or 53 percent, of the Nez Perce-Clearwater. The federally listed Spalding's catchfly occurs at one location in this area that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. There are 116 known occurrences of 18 at-risk plant species within the footprint of this protected area.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include more quality habitat in all habitat guilds. Alternative W offers more protected area than all other alternatives. While alternatives with higher acreage in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

Less protected roadless areas contain approximately 627,769 acres, or 16 percent, of the Nez Perce-Clearwater under Alternative W. Whitebark pine occurs in all montane areas. There are 50 occurrences containing 11 at-risk plant species in this management area.

Due to reduced ground disturbance and weed spread vector potential offered by more restricted management, these areas include more quality habitat in all habitat guilds. Alternative W offers less protected area in this category than all other alternatives. While alternatives with higher acreage in non-wilderness recommended roadless areas would allow fewer, more restricted activities that may affect species of concern, they provide a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are 1,238,907 acres of the Nez Perce-Clearwater, or about 31 percent, proposed as suitable for timber production under this alternative. The federally listed Spalding's catchfly occurs at two locations in this management area that is subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine potentially occurs where sufficient elevations are found. The emphasis on timber production in these areas increases threats from habitat fragmentation to 26 species of conservation concern representing 201 occurrences from potential management related activity.

Due to increased vegetation management of these grounds, there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is virtually the same under all alternatives, with the Preferred Alternative being slightly less than Alternative X and slightly more than Alternative W, Alternative Z, Alternative Y and the No Action Alternative, in that order. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. Such restoration would maintain a more natural and diverse component of vegetation types. In addition, increased levels of survey work and improved access would lead to an increase in documentation of occurrences. The at-risk plant species would be protected by policy and Land Management Plan components during management activities which will allow for their persistence in the plan area.

Effects of Alternative X

Undeveloped and more protected areas comprise about 1,253,640 acres, or 32 percent, of the Nez Perce-Clearwater. The federally listed Spalding's catchfly occurs at one location in this area that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. There are 116 known occurrences containing 18 at-risk plant species in this protected area footprint.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include quality habitat in all habitat guilds. Alternative X offers less of the more protected area than all other alternatives. While ground in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

Less protected roadless areas comprise about 1,441,086 acres, or 37 percent, of the Nez Perce-Clearwater under Alternative X. Whitebark pine occurs in all montane areas. There are 50 occurrences containing 11 plant at-risk species in this management area.

Due to reduced ground disturbance and weed spread vector potential offered by more restricted management, these areas include quality habitat in all habitat guilds. Alternative X offers more protected area in this category than all other alternatives, being followed in order by the No Action Alternative, the Preferred Alternative, Alternative Y, Alternative Z, and Alternative W. While alternatives with higher acreage in this area would allow fewer, more restricted activities that may affect species of concern, they provide a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are 1,243,856 acres, or 32 percent, of the Nez Perce-Clearwater proposed as suitable for timber production under this alternative. The federally listed Spalding's catchfly occurs at two locations in this management area that is subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine potentially occurs where sufficient elevations are found. The emphasis on timber production in these areas increases threats from habitat fragmentation to 26 species of conservation concern representing 201 occurrences from potential management related activity.

Due to increased vegetation management of these grounds there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is virtually the same under all alternatives, with Alternative X having slightly more acres than the other alternatives followed in order by the Preferred Alternative, Alternative W, Alternative Z, Alternative Y, and the No Action Alternative. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. Such restoration would maintain a more natural and diverse component of vegetation types. In addition, increased levels of survey work and improved access would lead to an increase in documentation of occurrences. The at-risk plant species would be protected by policy and Land Management Plan components during management activities which will allow for their persistence in the plan area.

Effects of Alternative Y

Undeveloped and more protected areas comprise about 1,557,603 acres, or 40 percent, of the Nez Perce-Clearwater. The federally listed Spalding's catchfly occurs at one location in this area that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. There are 116 known occurrences containing 18 at-risk plant species in this protected area footprint.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include quality habitat in all habitat guilds. Alternative Y offers less protected area than Alternative W, and Alternative Z but more than the Preferred Alternative, the No Action Alternative, and Alternative X. While alternatives with higher acreage in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

Less protected, non-recommended wilderness, roadless areas comprise of about 1,161,501 acres, or 29 percent, of the Nez Perce-Clearwater under Alternative Y. Whitebark pine occurs in all montane areas. There are 50 occurrences containing 11 plant at-risk species in this management area.

Due to reduced ground disturbance and weed spread vector potential offered by more restricted management, these areas include habitat in all habitat guilds. Alternative Y offers less protected area in this management area than Alternative X, the No Action Alternative, and the Preferred Alternative but more than Alternative Z or Alternative W. While alternatives with higher acreage in roadless areas of this category would allow fewer, more restricted activities that may affect species of concern, they provide a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are 1,219,952 acres, or 31 percent, of the Nez Perce-Clearwater proposed as suitable for timber production under this alternative. The federally listed Spalding's catchfly occurs at two locations in this management area that is subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine potentially occurs where sufficient elevations are found. The emphasis on timber production in these areas increases threats from habitat fragmentation to 26 species of conservation concern representing 201 occurrences from potential management related activity.

Due to increased vegetation management of these grounds, there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is virtually the same under all alternatives, with Alternative Y having slightly less acreage than Alternative X, the Preferred Alternative, Alternative W, and Alternative Z but slightly more than the No Action Alternative. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. Such restoration would maintain a more natural and diverse component of vegetation types. Such restoration would maintain a more natural and diverse component of vegetation types. In addition, increased levels of survey work and improved access would lead to an increase in documentation of occurrences. The at-risk plant species would be protected by policy and Land Management Plan components during management activities which will allow for their persistence in the plan area.

Effects of Alternative Z

Undeveloped and more protected areas comprise 1,815,279 acres, or 46 percent, of the Nez Perce-Clearwater. The federally listed Spalding's catchfly occurs at one location in this area that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. There are 116 known occurrences containing 18 species of conservation concern plant species in this protected area footprint.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include quality habitat in all habitat guilds. Alternative Z offers less protected area than Alternative W but more than Alternative Y, the Preferred Alternative, the No Action Alternative, and Alternative X. While alternatives with higher acreage in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

Less protected, non-recommended wilderness, roadless areas comprise about 890,597 acres, or 23 percent, of the Nez Perce-Clearwater under Alternative Z. Whitebark pine occurs in all montane areas. There are 50 occurrences containing 11 plant at-risk species in this management area.

Due to reduced ground disturbance and weed spread vector potential offered by more restricted management, these areas include quality habitat in all habitat guilds. Alternative Z offers less protected area in this management area than Alternative X, the No Action Alternative, the Preferred Alternative, and Alternative Y, but more than Alternative W. While alternatives with higher acreage in roadless areas in this category would allow fewer, more restricted activities that may affect species of concern, they provide a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are just over 1,233,180 acres, or 31 percent, of the Nez Perce-Clearwater proposed as suitable for timber production under this alternative. The federally listed Spalding's catchfly occurs at two locations in this area that is subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine potentially occurs where sufficient elevations are found. The emphasis on timber production in these areas increases threats from habitat fragmentation to 26 species of conservation concern representing 201 occurrences from potential management related activity.

Due to increased vegetation management of these grounds, there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is virtually the same under all alternatives, with Alternative Z havening slightly fewer acres than Alternative X, the Preferred Alternative, and Alternative W but slightly more acres than Alternative Y and the No Action Alternative. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. Such restoration would maintain a more natural and diverse component of vegetation types. In addition, increased levels of survey work and improved access would lead to an increase in documentation of occurrences. The at-risk plant species would be protected by policy and Land Management Plan components during management activities which will allow for their persistence in the plan area.

Effects of the Preferred Alternative

Undeveloped and more protected areas in Alternative P comprise about 1,511,006 acres, or 38 percent, of the Nez Perce-Clearwater. The federally listed Spalding's catchfly occurs at one location in this area that is subjected to light grazing and potential weed infestations. Whitebark pine occurs in all montane protected areas. There are 96 known occurrences and 18 at-risk plant species within the footprint of this protected area.

Due to reduced ground disturbance and weed spread vector potential, these more protected areas include more quality habitat in all habitat guilds. The Preferred Alternative offers more protected area than the No Action Alternative and Alternative X but less protected area than Alternative W, Alternative Z, and Alternative Y. While alternatives with higher acreage in protected areas would host fewer management activities to affect rare plants, they are subject to unmanaged threats such as fires and have fewer opportunities for the documentation of occurrence and protection through plan components.

Less protected roadless areas contain approximately 1,187,710 acres, or 30 percent of the Nez Perce-Clearwater under Alternative P. Whitebark pine occurs in all montane areas. There are 14 species of conservation concern that total 47 occurrences in this management area.

Due to reduced ground disturbance and weed spread vector potential offered by more restricted management, these areas include more quality habitat in all habitat guilds. The Preferred Alternative offers less protected area in this category than Alternative W, Alternative Z, and Alternative Y but more than the No Action Alternative and Alternative X. While alternatives with higher acreage in non-wilderness recommended roadless areas would allow fewer, more restricted activities that may affect species of concern, they provide a more limited opportunity to respond to threats such as fire and provide less access to manage weeds. There is also a reduced opportunity for documentation of occurrence and protection through plan components.

There are 1,240,340 acres of the Nez Perce-Clearwater, or about 31 percent, proposed as suitable for timber production under this alternative. The federally listed Spalding's catchfly occurs at two locations in this area that are subjected to light grazing and potential weed infestations. It is unlikely to be affected by timber harvest. Whitebark pine does not occur as developed stands on timber production ground; however, where elevations are sufficient, scattered individuals may form trace occurrences within other forest types. The emphasis on timber production in these areas increases threats to 24 species of conservation concern representing 195 occurrences from potential management related activity.

Due to increased vegetation management of these grounds, there is an increased potential for effects to rare plant species through mechanical harm, habitat alteration, and increased dispersal and infestation of invasive species. These threats would be greatest in the moist forest habitat grouping but could affect all guilds. The amount of ground with this designation is very similar under all alternatives, with the Preferred Alternative being slightly less than Alternative X and slightly more than Alternative W, Alternative Z, Alternative Y, and the No Action Alternative, in that order. While occurrences on these grounds are generally subjected to the highest level of management threat, they are also subjected to increased levels of restoration that could provide species benefit. Such restoration would maintain a more natural and diverse component of vegetation types. In addition, increased levels of survey work and improved access would lead to an increase in documentation of occurrences. The at-risk plant species would be protected by policy and Land Management Plan components during management activities which will allow for their persistence in the plan area.

Cumulative Effects

The cumulative effects area includes lands within the proclaimed boundaries of the Nez Perce-Clearwater. Actions on adjacent nonfederal lands have a possibility to affect catchfly populations on National Forest System lands but likely only for those populations nearest the Nez Perce-Clearwater boundaries. It is not possible to state what actions are likely to occur on adjacent private lands, but it is assumed these lands would be managed as they are today. Nonfederal actions most likely to affect catchfly plants on adjacent National Forest System lands is invasive plant control on adjacent private lands, as well as county and state roads leading to and coursing through the national forests. Active weed management programs on adjacent private lands, as well state and local government roadside weed control, would likely benefit catchfly habitat on federal lands because fewer weed propagules would be available for transport, whether by people, vehicles, wind, or wildlife, to disperse into catchfly habitat. The effects of other management activities on adjacent private, state, and federal lands is expected to be confined to those lands and not overlap in time and space with catchfly populations on National Forest System lands.

Increasing Human Populations

Additional stressors that may increase in the future are increasing human population levels, both locally and nationally, with resulting increasing demands and pressures on public lands. As related to forest and vegetation conditions, these changes may lead to increased demands for commercial and non-commercial forest products, elevated importance of public lands in providing for habitat needs of species, and changing societal desires related to the mix of uses public lands should provide. The plan components are adequate to support persistence of at-risk plant populations and habitat on the Nez Perce-Clearwater as human populations and demands increase. However, population and use trends suggest not only that public land will play an increasingly important role in the conservation of these species in the future, but also that management to ensure recovery and prevention of federal listing of species will be an increasingly difficult challenge.

Adjacent Lands and Other Management Plans

Portions of the Nez Perce-Clearwater adjoin other National Forests, each having its own Forest Plan (or Land Management Plan). The adjacent forests include the Idaho Panhandle, Lolo, Bitterroot, Salmon–

Challis, Payette, and Wallowa–Whitman National Forests. Generally speaking, management of vegetation, including species of concern, is consistent across all national forests due to law, regulation, and policy. The cumulative effects would be that the management of at-risk plants and habitats would provide adequate protection to prevent species from decline or loss of persistence. The Nez Perce-Clearwater is also intermixed with lands of other ownerships that include private lands, other federal lands, and state lands.

Bureau of Land Management lands primarily to the west of the Nez Perce-Clearwater are managed by the Cottonwood field office through the 2009 Cottonwood Resource Management Plan. The plan is complementary to the Nez Perce-Clearwater Land Management Plan in terms of managing for multiple uses and sustaining healthy and functional ecosystems. Broadly speaking the plan would likely contribute toward similar general desired conditions as the Nez Perce–Clearwater Land Management Plan, with much of the management guidance having similar intent with respect to resource protections.

The Idaho Natural Heritage Program is a member of NatureServe, an international network of biological inventories known as natural heritage programs or conservation data centers that operate in all 50 United States, Canada, Latin America, and the Caribbean. They provide important tools from the Idaho Natural Heritage Databases, a system that allows locations and related information on rare species to be entered and shared for environmental review and conservation purposes. Lists of rare, unique, or vulnerable plants, animals, and biological communities are maintained by each heritage program.

The State of Idaho manages timberlands to maintain income for endowment trusts in accordance to the Idaho Forest Practices Act. The Idaho Department of Lands administers the Idaho Forest Practices Act of 1974 to promote active forest management and ensure that the health of forest soil, water, vegetation, wildlife, and aquatic habitats. While the State Natural Heritage Program maintains a database of species of concern, only species federally listed by the U.S. Fish and Wildlife Service have official status or management protections on state lands. While maintaining economically sustainable products, the Idaho Forest Action Plan seeks to promote forests that are diverse and resilient to changes in climate and human activities and maintain ecosystem benefits.

No at-risk plant protection is provided as part of any area county resource plans. These plans generally acknowledge the importance of special habitats such as wetlands, riparian areas, and grasslands in supporting species diversity ecosystem function, which provides a course filter benefit for all at-risk species in such habitats. At-risk plants on private lands are considered to be at greater risk of local extirpation due to lack of protections. Such county plans generally are focused on the effective control and reduction of noxious weeds. Successful efforts in weed control would contribute to the maintenance or improvement of habitats important to ecosystem function and at-risk species where they occur.

Climate Change

Climate change is expected to profoundly alter vegetation structure and composition, terrestrial ecosystem processes, and the delivery of important ecosystem services over the next century (Kerns et al. 2017). Climate influences the spatial distribution of major vegetation biomes, the abundance of species and communities within biomes, biotic interactions, and the geographic ranges of individual species. Researchers speculate that a warming climate will alter precipitation patterns, with some regions becoming drier and others becoming wetter. Within the Pacific Northwest, a recent model predicts warmer and wetter winters in 80 years. Being stationary, plants must migrate through dispersal, colonization, and recruitment strategies, a relatively slow process compared to mobile organisms. Some researchers believe that plant species will not be able to migrate at a pace dictated by a warming climate, which would isolate and eventually doom some species, unless new adaptations arise to cope with a changing environment. Under the influence of changing climate, if droughts and warmer winters continue, agents such as insects and disease will likely show increased levels of activity. Mortality from these factors and drought would likely lead to fires that burn with greater intensity when weather favorable to high intensity fires develops. Such events may further reduce potential habitats and limit ability to species to respond and migrate.

Primary strategies to address climate change threats focus on increasing resilience to ecological disturbance, such as wildfire, insects, and nonnative species (Halofsky and Peterson 2016). Rare and disjunct species and communities require adaptation strategies and tactics focused on encouraging regeneration, preventing damage from disturbance, and establishing refugia. Overall, the protection and restoration objectives and practices described in the Land Management Plan will potentially promote resilience and conservation.

Effects to Resource from Other Resources

The following discussion focuses on effects to at-risk plant species presented by the management of other resources areas. For each resource, the general effects of plan components that may contribute to or mitigate effects or maintain general conditions to the benefit of at-risk species or habitats are presented. While effects are reviewed, most individual plan components are not cited as the effects are small or indirect and there are too many to list. Plan components that more directly apply to at-risk species or habitat are specifically listed and discussed.

Timber Management

Timber harvest is most likely to occur on lands identified as suitable for timber production. Harvest increases some threats to at-risk species but also can create a mosaic pattern on a landscape and promote early successional stands with some treatments, such as regeneration harvest. Typically, known at-risk species would receive site-specific protection following botanical reviews and surveys (Forest Service Manual 2670) and negative effects would be minimized; however, this only applies to sensitive species. This would continue to occur with the proposed plan components for at-risk species following project-level evaluation procedures that are not currently finalized.

All alternatives have varying amounts of land suitable for timber production, but the impact of timber plan components on at-risk species is consistent between action alternatives. The moist forest habitat guild would be most impacted by timber management, but all habitat guilds can be affected by timber production even if habitats guilds, such as aquatic, subalpine, meadow, rocky or grassland, are not directly harvested for timber. Mechanical activities include vegetation management treatments, whether for restoration or to meet timber production objectives. Activities, such as logging, can have impacts to plants and plant habitat through canopy removal, soil disturbance and erosion, and stream sedimentation. In addition, mechanical activities for vegetation treatment may require road building. Roads increase access to sensitive habitats and can fragment habitat, thus, providing an avenue for invasive plant species. Reconstruction and maintenance of designated roads can directly or indirectly affect plant populations by introducing competitive weeds and altering availability of light, nutrients, and moisture. Sudden changes in seral stage, or an abundance of early seral stages, also reduce the available habitats for those plants that require mid-to-late seral stages. However, those species that prefer openings, early seral stages, or some ground disturbance could benefit from various levels of mechanical activities.

As a result of plan components and policies, at-risk species and their respective habitats would be considered during vegetation management and are expected to be maintained and continue supporting at-risk plant species despite the potential for impacts in areas used for timber production. The new plan is more explicit regarding resource protections, though similar guides and policies are applied under the old plans. Habitat quality would remain similar between the No Action Alternative and action alternatives for at-risk species in all habitat guilds under the timber plan components. Threats would be reduced for at-risk plants by the action alternatives plan components by including additional language to protect sensitive habitats.

Several plan components express a desired condition to maintain whitebark pine in appropriate habitats on the Nez Perce-Clearwater. These include, FW-DC-FOR-09, FW-DC-FOR-10, MA1-DC-FOR-09, MA2-DC-FOR-09, MA3-DC-FOR-07, and MA3-DC-FOR-10. Specific objectives directing the restoration of cold forest types that support successional stages that could benefit whitebark pine include MA2-OBJ-FOR-02 027, MA3-OBJ-FOR-03, and MA3-OBJ-FOR-04. MA2-OBJ-FOR-01 and MA2-OBJ FOR-02 specifically calls for increased planting of whitebark pine. Open Ponderosa pine forests, which support species of the grassland guild, would be supported by GA-DC-SR-02 and FW-DC-FOR-02. There are numerous plan components under this resource that will contribute to an array of forest cover types and structure to support general floral diversity.

Vegetation Management

All habitat guilds are potentially affected by the action alternative's vegetation desired conditions. Broadly, the desired conditions for terrestrial vegetation on the Nez Perce-Clearwater are characterized by improvements in species composition, desirable densities, and general forest health and condition; vigorous non-forested plant communities; and maintaining native biodiversity on the landscape. The desired conditions are consistent with the Forest Service's understanding of the natural range of variation and are most likely to be resilient in the future given expected drivers, such as climate change, drought, vegetation succession, wildfire, insects and disease, and the demands of people. Desired conditions for vegetation support native species and habitats within their natural range of variation, including at-risk species.

Ground disturbing activities and changes in site conditions that could impact at-risk species are likely to result from the terrestrial vegetation plan components. The restoration of historical fire regimes and restoration of conditions towards historical range of variation with a range of seral stages for different potential vegetation groups may benefit some at-risk species in the long-term.

These revised vegetation plan components are expected to maintain and continue supporting at-risk plant species on the Nez Perce-Clearwater. Generally, habitat quality would be maintained or improved for at-risk species in all habitat guilds under the plan components in the action alternatives. Threats would remain similar for at-risk plants in regard to vegetation plan components. While some occurrences may be impacted, generally activities would maintain a more diverse and natural range of vegetative habitats which would benefit at-risk species.

Plan components that maintain older forests are beneficial to the persistence of at-risk species in the moist forest guild in particular. Contributing components include MA3-STD-FOR-01, MA3-GDL-FOR-02, MA3-GDL-FOR-03, MA3-GDL-FOR-04, and MA3-DC-FOR-10. FW-DC-FOR-01 calls for the persistence of aspen across its range on the Nez Perce-Clearwater and the objective. FW-OBJ-FOR-01 calls for aspen restoration across the Nez Perce-Clearwater. Aspen support unusually diverse floral communities important to species diversity and pollinators. Desired conditions that support grasslands, aquatic, meadow, and subalpine guilds that support at-risk species include FW-DC-GS-01-08. Plan components that are focused on special habitats, diversity, and endemic species include FW-DC-TE-01 through -05. FW-GDL-TE-01 states that uncommon habitat elements should be conserved to allow rare and endemic plant communities to persist.

Fire and Fuels Management

Under all alternatives fire would be used as a tool to accomplish management goals and objectives. The objectives for fuel reduction are usually complementary to the other desired vegetation conditions, including those beneficial to at-risk species, especially as related to forest resiliency. There are several factors that are important to consider with regard to at-risk plants. One factor that is important to some rare plants is the timing and placement of prescribed burns. For example, the use of prescribed fire in the spring has potential to impact some rare plants that are not adapted to fire at this time of year and spring burning can interfere with flowering, fruiting, pollinator availability, and other physiological impacts. Other at-risk species prefer spring burning events due to a lower rate of litter build-up which reduced fire severity and increases survival. Considering at-risk species during the planning process (FSM 2670) should ensure that the timing and placement of prescribed burns is used to maintain at-risk plant populations as much as possible by timing when phenologically appropriate and avoiding populations of species that could be adversely affected by fire.

Another factor is the risk of high severity wildfire resulting from high fuel loads. The current condition is an overall high risk of high severity burns across much of the Nez Perce-Clearwater due to high fuels load, which has resulted from past fire suppression and the outbreak of bark beetle infestations. Without some prescribed fire introduced to mitigate the threat of high severity fire, at-risk species populations are susceptible to being eliminated or reduced in areas on the landscape in all forested habitat guilds. Many species tolerate, and in fact require, frequent low severity fire to maintain populations on the landscape. Stand replacing fires have the potential to kill at-risk plants and reduce or eliminate seed banks, making reestablishment difficult or even impossible without additional seed sources brought in.

Another factor to consider is that some at-risk species require regular fire to maintain early successional conditions that supports known occurrences. This includes species in the wetland-riparian, meadow, grassland, and savanna habitat and transitional habitat guilds. Potentially, other habitats could also be involved in the future depending upon species specific requirements, which can change depending on new best available science and adjustments to the species of conservation concern list. The species that require fire typically need low severity fire to maintain sensitive habitats. The reduction of fire has generally reduced the amount of available habitat for such species. In general, most plant species would benefit by the restoration of more historical fire regimes. For those rare plants that thrive in open areas created by fires, using fire to help restore a more natural fire regime could benefit those species in the long-term. There are also impacts to plants associated with wildfire suppression activities, such as fire line construction and other mechanical activities, reforestation following fire, and the increased potential for the spread of noxious weeds.

At-risk plants have various reactions to fire. As a result of these plan components, all habitat guilds are generally expected to be maintained and continue supporting at-risk plant species, including the species that are currently on the sensitive plant list but that would not be specifically protected as a species of conservation concern once the new plan is implemented. Analysis prior to implementation allows for appropriate mitigation to be developed when necessary to account for at-risk plant species.

Plan component MA2-OBJ-FOR-02 seek to restore cold forests through fire. This would benefit habitat conditions favoring whitebark pine. Desired conditions that seek to support ecosystem function and meet desired conditions of other resources through a range of burn conditions, fire intensities, and fuel conditions of more historic fire regimes include FW-DC-FIRE-01 and FW-DC-FIRE-02. Also, the goal of building understanding of fire's role in sustaining fire adapted ecosystems, as stated in FW-GL-FIRE-03, is important to open plant guilds where fire is a component. Fire guideline FW-GDL-FIRE-02 is designed to decrease the expansion of invasive weeds are important for all plant guilds but particularly grassland and transitional habitats.

Watershed, Riparian and Aquatic Management

The threats to associated wetland and riparian and meadow at-risk plant species include changes to hydrologic function and nutrient alterations. Mechanical vegetation treatments, off-road vehicles, roads and trails, livestock grazing, and high severity wildfires are some of the actions that affect the hydrologic regimes or nutrient inputs. The action alternatives include desired conditions that would specifically support at-risk plant habitat in the previously mentioned guilds that overlap with aquatic ecosystems. The revised plan components have additional protection measures and an increased emphasis on the restoration and maintenance of riparian and aquatic resources.

As a result of these plan components, wetland-riparian habitat guilds are expected to be maintained and continue supporting all at-risk plant species that occur in these habitats. The revised plan is more explicit on aquatic ecosystems protections, connectivity in riparian habitats, and groundwater-dependent systems, in addition to following state guidelines and best management practices in the previous plans.

These plan components are expected to contribute to stable populations for all at-risk species in the moist and wet habitats by preserving required habitat characteristics for these species. Habitat quality would be maintained or improve for all at-risk species in the meadow and wetland and riparian habitat guilds.

Specific plan components that more directly benefit at-risk plants in wetland, riparian, and meadow habitats include FW-DC-WTR-02, which contributes to habitat connectivity that aids potential plant dispersal for both aquatic species and forest species through preserved riparian areas. FW-DC-WTR-07 contributes to instream flows sufficient to sustain riparian, aquatic, and wetland habitats. FW-DC-WTR-08 seeks to maintain groundwater dependent ecosystems, including fens, wetlands, seeps, springs, and riparian habitats, which are all habitats that support at-risk species. FW-GDL-ARINF-08 states that wetlands and seasonally wet meadows should be avoided when developing roads and landings and drainage features should maintain wetland functions and characteristics.

Wildlife Management

Several of the objectives relating to wildlife direction complement the at-risk plant needs by describing a desired condition to manage vegetation to approximate natural succession and disturbance processes and provide a mosaic of habitat conditions through time. These components would generally contribute to the maintenance of diverse habitats for at-risk species. Many forestlands plan components contribute to these overall desired vegetative conditions as well.

FW-GL-WL-01, FW-DC-WL-01, and FW-DC-WL-02 encourages cooperation and collaboration across multiple agencies to work on a variety of planning and management tasks to work toward recovery of federally listed species. While this component is geared mainly to wildlife, the benefits extend to all at-risk listed species. FW-DC-WL-03 and FW-GDL-WL-01 promote the maintenance vegetative patterns to allow for connectivity for wildlife. Such connectivity of habitat also benefits dispersal and genetic exchange of plant species dependent on such habitats. Plan components for fisher (FW-DC-WL-04) maintain warm, moist potential vegetation type habitats that would also benefit species of the mesic forest plant guild. Several elk objectives in Management Area 2 and 3 will promote habitats that may benefit at-risk plant species in the transitional guild on parts of the Nez Perce-Clearwater.

Land Allocation

The alternatives vary in quantity and location of management areas. Designated wilderness areas, wild and scenic rivers, historic sites, and research natural areas do not vary in location or area. The alternatives vary in the number of inventoried roadless areas that are retained or recommended for wilderness. Management Area 3 changes slightly across the alternatives but is largely consistent.

The comparison of alternatives based upon threat categories and management areas is provided in the alternative discussions. Alternative W offers the most area protected in areas that would see the fewest management activities. These more undeveloped and protected areas would generally protect at-risk plant habitat from ground disturbing threats and development, and these areas would be managed allowing natural fire regimes to contribute to a mosaic of different seral stages and diversity habitats as much as possible. An increase in these protected areas decreases threats to at-risk plants overall from ground disturbing activities, such as vegetation projects, some motorized and mechanized access, and weed spread vectors, while promoting a naturally managed system that has the potential to improve the mosaic pattern on the landscape. However, species in the mesic forest guild that require mid-late seral forests could see less habitat in protected areas due to large and extensive wildfires that have reduced such habitats in wilderness. Management Area 3 allocated ground is subjected to more vegetation management, but the needs of at-risk species can be incorporated in planning efforts to protect them when necessary. See the designated areas sections for more details on the management differences between these land allocations.

All action alternatives would have the ability to achieve desired vegetation conditions within inventoried roadless areas through the use of vegetation treatments. All have Land Management Plan direction that allow restoration activities to occur as long as the laws and policies governing such activities are met. Anticipated vegetation treatment activities would often be associated with forest restoration and salvage from existing roads, prescribed fire, and restoration of higher elevation whitebark pine forest communities. There may be other treatments occurring to achieve restoration objectives outlined in the plan components.

Municipal watersheds are protected for water sources (FW-DC-MWTR-01), which would also protect maintenance of habitat for at-risk plant species in the mesic forest guild and potentially other habitat groups that maybe present. Several wilderness components direct management that maintains wilderness characteristics which exclude many activities that are potentially harmful to at-risk species of all guilds. Similarly designated wild and scenic river components protect the river corridors and the habitats contained from activities that may interfere with the protection and enhancement of the values for which the river was designated. In the case of suitable wild and scenic rivers, vegetation management is only allowed to protect users or identified outstandingly remarkable values; or protect, restore, or enhance the river environment (MA2-SUIT-E&SWSR-02). Roadless areas provide undisturbed habitat for several at-risk species in all plant guilds (MA2-DC-IRA-01) and enable dispersal and genetic exchange through habitat connectivity (MA2-DC-IRA-02). Research Natural Areas contribute to ecological sustainability and biological diversity through inclusion of assigned vegetative communities as well as protection of at-risk species and unusual elements (MA2-DC-RNA-01). Disturbance from forest products for personal and commercial uses are not authorized in research natural areas (MA2-STD-RNA-01 and -02). Research natural areas protect examples of all at-risk species guilds. Several special interest areas are established protect and promote unusual or diverse botanical settings. Many of these contain occurrences of threatened or species of conservation concern and many good examples of at-risk plant guilds.

Access and Recreation Management

Motorized and mechanical means of transport impact rare plant occurrences within road prisms and road maintenance activities can remove habitat in these areas. Vehicles that travel off-road can disturb at-risk plant occurrences and compress soil, eliminating habitat along designated travel routes and roads open to motorized use. In addition, motorized routes are primary weed spread vectors.

Recreation impacts can include trampling, both by hikers and off-road vehicle use. Road building and the development of campgrounds and other facilities used by recreationists also contribute to plant impacts, as these developments make more areas accessible and concentrate use. Winter motorized recreation may damage portions of whitebark pine that protrude above the snow. Dispersed camping and recreation have similar impacts, which are more difficult to monitor. Parking areas, particularly undesignated areas, pose similar impacts to plants. In addition, there can be long-term impacts of bisecting a rare plant population with a road or similar feature and affecting the reproduction and/or plant dispersal. Roads and trails for recreational use can contribute to the spread of noxious weeds and increase the accessibility of areas to livestock, as well as native ungulates, which in turn can increase the impacts of trampling, herbivory, and congregation.

The plan components are expected to contribute to the maintenance of at-risk populations on the Nez Perce-Clearwater by including protections associated with recreation opportunities. Most habitat guilds are protected from recreational related damages by other components, reducing risk for species that occur in with these habitats. Wilderness areas and Wild and Scenic Rivers are still protected under national guidance and would continue regardless of alternative. Under the recreation plan components, at-risk species habitat quality would remain similar between the No Action Alternative and action alternatives, with the most protections coming under Alternative W due to increased recommended wilderness.

Minerals Management

Development of energy and mineral resources has the potential to adversely impact special status species through all phases of development. Impacts include mortality to individual at-risk plants, or entire populations, as well as habitat loss and fragmentation. Under plan components, at-risk species habitat quality would remain similar between the No Action Alternative and action alternatives. Threats would be reduced for at-risk plants by the action alternatives plan components including FW-GDL-AREM-01, which calls for avoidance of wetlands and riparian areas in mineral operations and requires the use of native revegetation efforts as part of operations (FW-STD-AREM-01) to reduce invasive species.

Livestock Grazing

All habitat guilds have some potential to be impacted by livestock, which when grazed improperly can cause hydrologic changes, trampling to individual species, habitat degradation through invasive species introduction, and soil impacts. Habitat guilds most likely impacted by livestock grazing include riparian habitats, meadows, transitional habitats, and grasslands. The at-risk plant species would be protected by Forest Service manual guidelines and plan components during project level planning to prevent or mitigate negative impacts.

As a result of these plan components, the effected guilds are expected to be maintained and to continue supporting at-risk plant species in livestock allotments. There would be opportunities in the future to restore habitats that have become degraded over time. The language in the new plan is more explicit than the other plans but management direction to preserve habitat quality is generally similar. Habitat quality would improve with the action alternatives for at-risk species in all habitat guilds due to grazing components to improve or maintain quality habitat.

FW-GDL-GRZ-01 seeks to reduce impacts resulting from livestock use to benefit riparian areas, meadows, and other habitats that may be important to species of conservation concern. FW-GDL-GRZ-02 states that allotment planning should include measures to protect federally listed plant species and evaluate habitats for other at-risk species and adjust prescriptions as necessary to ensure viability. FW-GDL-GRZ-03 directs that utilization occurs at levels that will maintain vegetative vigor and community health and planning considers the condition, timing, and use of the resource along with other values of the area. This is important to maintain overall health of grassland habitats to prevent overall habitat degradation which harms at-risk species.

The guidelines FW-GDL-GRZ-01, FW-GDL-GRZ-02, and FW-GDL-GRZ-03 direct the mitigation or relocation of livestock salting through revised allotment management plans to avoid impacts to riparian management zones. Such activity would benefit at-risk plant species in the riparian and moist forest guilds due to a high affinity for some species to occur in such areas.

Invasive Species Management

Invasive species can have a major impact on at-risk species on the Nez Perce-Clearwater. In general, increased ground disturbance corresponds with increased weed spread. Roads, trails, livestock, and canopy reduction can provide ideal pathways for the introduction of exotic and non-native species. Introduced, invasive plant species can displace at-risk species through competitive displacement, especially in the grassland and rocky guilds. Wetlands, subalpine forests, and moist forests are largely closed to most significant weed invasions, though localized events can occur. Competition from invasive, non-native species and noxious weeds can result in the loss of habitat, loss of native pollinators, and decreased rare plant species viability. Impacts from management activities include herbicide spraying and mechanical ground disturbance to control noxious weeds once they gain a foothold. All habitat guilds, particularly the grassland guild, are expected to benefit from the reduction of invasive species. Such reduction would contribute to stabilize at-risk plant populations on the Nez Perce-Clearwater. The action alternatives provide similar protections and guidelines for invasive species treatment as the existing plans; however, additional plan components in the action alternatives are expected to increase the opportunities for at-risk plant restoration on the Nez Perce-Clearwater.

Plan components that would most benefit at-risk species through reduced weed infestation include FW-DC-INV-01, which calls for invasive species to be either not present or occur at low levels. FW-OBJ-INV-01 call for treating 6,000 acres of weeds annually to contain or reduce weed density, infestation area, or occurrence with emphasis on early detection and rapid response to new invaders. FW-GDL-INV-01 seek to implement project level design features that will reduce weed establishment and expansion. There are many soil plan components that will benefit at-risk species through a reduction of soil disturbance that will offer less opportunity for weed establishment. FW-STD-AREM-01 requires the use of native species in revegetation efforts as part of mineral operations to prevent or reduce weed invasion.

Soils Management

All habitat guilds depend on soil quality and productivity within their respective habitats. Forest Service activities that lead to soil compaction or soil contamination with toxic materials have the potential to negatively impact at-risk plant habitat. Some activities that can threaten soil quality include mechanized vegetation treatments, roads and trails, recreation, grazing, and off-road vehicles. As a result of the soils plan components, all habitat guilds are expected to maintain soil quality and productivity, which would contribute to stable at-risk plant populations on the Nez Perce-Clearwater. The plan components provide protections and guidelines for soil productivity which would support rare plant habitats and populations.

Desired condition FW-DC-GS-06 describes the importance of mollisol soils in healthy grasslands that are important to many species of concern. There are many soil plan components that will benefit at-risk species through a reduction of soil disturbance that will offer less opportunity for weed establishment.

Pollinators

Invertebrate pollinators are crucial components of functioning ecosystems. There is evidence that many species may be in decline due to a variety of factors. Broadly, the desired conditions in the action alternatives increase habitat quality for invertebrate pollinator species. All alternatives provide habitat for pollinator species in the plan area with native plant species, a variety of habitats, and large areas without the habitat fragmentation that has become characteristic of agricultural and developed land. All action alternatives include plan components for other resources that improve habitat for pollinators in the plan area that contribute to increased habitat quality. Forestwide terrestrial ecosystem components and forestlands components are particularly important for restoring and maintaining habitats and successional stages that will benefit pollinators. Activities that benefit habitat for pollinators also benefit at-risk plant species through increased habitat diversity and increased pollinator activity for those species.

At-Risk Plants

Plan components that are relevant to at-risk plants are the same for each action alternative. As a result of these plan components, at-risk plant populations in all habitat guilds are expected to persist with opportunities to restore sites if conditions warrant. Most plan components cited above provide a course filter approach to protect at-risk plant species and their habitats. For some species needs, the listed components may not fully address species persistence and a fine filter approach is needed. FW-DC-GS-07 seeks to maintain Dasynotus and Pacific dogwood in transitional habitats that may be threatened by the progression of succession. FW-DC-GS-08 seeks to maintain Douglas clover and sticky goldenweed in special meadow habitats with unique needs on the Palouse Ranger District.

Some plan components reviewed with a course filter approach in the above discussions should also be included here as they are particularly important and intended largely for at-risk plant species dependent on specialized habitats. FW-DC-TE-01 accounts for uncommon habitat elements are preserved to support the long-term persistence of rare and endemic species with very narrow or specific habitats and limited distribution. This applies to several species of conservation concern plant species. FW-DC-TE-02 is specifically for the maintenance of peatlands and other wetland habitats that support many rare and unique species. FW-DC-TE-04 promotes the composition, structure, function, and connectivity of native plant communities are appropriate for a given landscape and climatic setting. FW-GDL-TE-01 encourages conservation of species found near uncommon habitats elements described in FW-DC-TE-01 and that activities to not remove or alter habitats to improve conditions for terrestrial plant or invertebrate animal communities that have been assigned a NatureServe ranking of G1 globally critically imperiled or G2 globally imperiled. FW-DC-GS-01, FW-DC-GS-02, and FW-DE-GS-06 are particularly important for at-risk plants in the grassland guild and FW-DC-GS-04 is important for persistence of species in wetland and meadow guilds.

There are unknowns about future species of conservation concern policy. The Regional Forester has defined sensitive species policy, but Forest Service manual policy is not yet available for species of conservation concern. An interim management policy is expected to become available prior to the revised manual direction.

Summary of Consequences

Table 93 summarizes the number of species reviewed in each protection category across the alternatives. The occurrence of the threatened Spalding's catchfly is the same regardless of the alternative. The threatened species, Macfarlane's four-o'clock, has no occurrences on the Nez Perce-Clearwater and is thus excluded from the table. Whitebark pine occurrences have not been numbered but it occurs in all categories regardless of alternative. In several cases, occurrences cross area boundaries that vary with each alternative. This is especially true with large occurrences or occurrences with low mapping precision. This results in many occurrences being mapped and counted in more than one category. Thus, the counted occurrence totals are not consistent across the alternatives.

Conclusion

All at-risk plant species are expected to maintain viable occurrences on the Nez Perce-Clearwater under all alternatives due to Forest Service Manual direction in the No Action Alternative and the plan components in the action alternatives. The direction and plan components will ensure that species of conservation concern and federally listed species are considered during ground-disturbing activities. Habitat quality and threats vary slightly between each alternative due to different land allocations through differences in acreage of the more undeveloped and protected areas and proposed land suitable for timber production.

The No Action Alternative would maintain the existing separate plans for the Clearwater National Forest and Nez Perce National Forest. While all plants are expected to remain viable on the Nez Perce-Clearwater as a result of this alternative due to Forest Service manual policy, there are fewer plan components in the current plans that protect some species' habitat. There are no plan components for specific species needs.

The action alternatives provide considerable changes to forestwide plan direction that apply to each at-risk species' habitat on the Nez Perce-Clearwater. The revised plan components provide additional protections to at-risk plant habitats. The variations in plan components between the action alternatives are not expected to affect at-risk species differently because all plan components relevant to at-risk plant species remain the same between the action alternatives. The area proposed as suitable for timber production does not vary considerably by alternative so there is limited difference among any of the alternatives regarding potential effects to at-risk plant species.

The number of species and occurrences are highest in Management Area 3 because the front areas provide more diverse habitats that are important to the distribution of the particular plant species reviewed. Also, because these areas have supported more past projects and provided more opportunity for survey as part of project analysis, documentation of occurrences has been more thorough in these areas. Rare plant occurrence in wilderness and backcountry areas have been documented less due to less access and project level review. The most protected areas only approach Management Area 3 ground in numbers of occurrences due to the inclusion of research natural areas in that category. These small areas are unusually rich ecologically and have received a disproportionate review and documentation as centers of study and research.

While wilderness, recommended wilderness, and other more protected areas are generally considered to have fewer disturbances, species dependent on older forests may actually be more impacted in these settings due to lack of fire suppression and the increasing prevalence of early seral forests following fire. Management Area 3 ground will host more impactive activities; however, the implementation of plan

Table 93. Rare plant indicator comparison of alternatives

Measurement Indicator	No Action Alternative	Alternative W	Alternative X	Alternative Y	Alternative Z	Preferred Alternative
Silene spaldingii Spalding's catchfly	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences	Most Protected 1 occurrence Less Protected No occurrences Timber Production 2 occurrences
Pinus albicaulis Whitebark pine	Several occurrences	Several occurrences	Several occurrences	Several occurrences	Several occurrences	Several occurrences
Regional Forester Sensitive Species (RFSS)	Most Protected 28 species 162 occurrences Less Protected 25 species 181 occurrences Timber Production 29 species 319 occurrences	No RFSS	No RFSS	No RFSS	No RFSS	No RFSS
Species of Conservation Concern	None	Most Protected 18 species 116 occurrences Less Protected 11 species 50 occurrences Timber Production 26 species 201 occurrences	Most Protected 17 species 94 occurrences Less Protected 13 species 77 occurrences Timber Production 26 species 203 occurrences	Most Protected 18 species 111 occurrences Less Protected 11 species 75 occurrences Timber Production 25 species 190 occurrences	Most Protected 18 species 112 occurrences Less Protected 13 species 64 occurrences Timber Production 26 species 204 occurrences	Most Protected 18 species 96 occurrences Less Protected 14 species 47 occurrences Timber Production 24 species 195 occurrences

components will offer general resource protections that will benefit rare species through a course filter. Additionally, project level analysis may lead to more survey and site-specific protections when appropriate as well as the implementation of restoration activities that maintain or increase habitats that are suitable for some species of concern.

Determinations are provided for federally listed species, species of conservation concern, and sensitive species for all alternatives as follows:

Federally Listed and Proposed Species

The three federally listed species that are reviewed in projects on the Nez Perce-Clearwater are Macfarlane's four o'clock, Spalding's catchfly, and whitebark pine.

Macfarlane's four o'clock is addressed in projects when directed by the U.S. Fish and Wildlife Service. This inclusion is based upon occupied habitat that is very close to parts of the Forest or occurrence within particular counties. Based upon project level and landscape level survey and review, potentially suitable habitat for this species on the Nez Perce-Clearwater is unknown, of marginal quality, or is outside the local ranges of the species. The Forest will continue to review for this species as part of project level analysis as directed by the U.S. Fish and Wildlife Service.

Determination: No Effect on Macfarlane's four o'clock.

Spalding's catchfly occurs at three grassland locations on the Nez Perce-Clearwater. One occurrence is on ground in the most protected category, while the other two are on Management Area 3 ground. All three sites are potentially affected by invasive species, livestock and wildlife grazing, recreation, climate change, and general habitat degradation under all alternatives. Plan components will contribute to the protection and maintenance of the species and its habitat and project level consultation with the regulatory agency completed; however, there is potential for some plants to be subjected to some level of disturbance from a number or sources. These sites are subject to ongoing direct, indirect, and cumulative effects.

Determination: Likely to Adversely Affect Spalding's catchfly.

Whitebark pine is found at many locations on the Forest but primarily on Management Area 1 and Management Area 2 ground. Where sufficient elevations exist in Management Area 3, trace amounts of the species may occur, but developed stands are not expected. In this botanical analysis Management Area 1, and Management Area 2 approximately correspond to the most protected and less protected ground respectively. Factors contributing the species decline will continue through direct, indirect, and cumulative effects. Implementation of some plan components to treat vegetation in suitable habitats and restore whitebark pine may harm some individual trees but would be implemented to the benefit of the species and its habitat and increase the likelihood of persistence of the species on the landscape.

Determination: Likely to Adversely Affect whitebark pine.

Species of Conservation Concern

Indirect and cumulative effects for plant species of conservation (SCC) concern were analyzed using a review of effects of potential management actions and plan components to habitat guilds and a comparison of occurrences in general management categories across alternatives.

There are seven habitat guilds. General effects to these guilds and the species involved were provided in the discussion of guilds in this analysis. The number of species per guild is provided below:

- Grasslands – 7 species
- Meadows – 5 species
- Mesic forest – 12 species
- Rocky habitats – 7 species
- Subalpine forests – 1 species
- Transitional habitats – 2 species
- Wetlands – 2 species

Some species occur in more than one guild.

The No Action Alternative provides the least direction to protect habitats for rare plant species, though agency policy in the Forest Service manual provides adequate direction to maintain viable populations of these species. The No Action Alternative recognizes sensitive species rather than species of conservation concern. All action alternatives include additional plan components to maintain at-risk plant habitat in the plan and are expected to provide additional beneficial impacts to habitat quality for at-risk plant species in the plan area. The comparison between alternatives is largely qualitative and subsequent project analyses would evaluate impacts to these species designated as species of conservation concern.

Species and occurrences were also counted individually between alternatives to compare the relative potential for impacts by threat categories important to the plant species. Threats to species of conservation concern from vegetation management is very similar across all action alternatives due to the small difference in the area designated as Management Area 3 and overarching policies and at-risk plant components protecting these species during project activities. Potential management disturbances would be much less in the more protected categories where management is absent or more restricted.

Determination: May impact individuals but would not contribute toward a trend for federal listing or loss of viability.

Sensitive Plant Species Currently on the Regional Forester's Sensitive List

Of the 41 plant species currently identified as sensitive by the regional forester that are known or suspected to occur on the Nez Perce-Clearwater, 23 have been identified as species of conservation concern by the regional forester. Whitebark pine was on the sensitive list but now as a threatened species it is included as an at-risk, federally listed species rather than included with species of conservation concern. Removing whitebark pine and the 23 species of conservation concern from the Regional Forester Sensitive Species list, leaves 18 sensitive plant species with no status under the revised plan.

Indirect and cumulative effects for the Regional Forester Sensitive Species list were analyzed using habitat guilds to compare plan components and general impacts of habitat management. Of the remaining 18 sensitive species that are not designated species of conservation concern, three are not known to occur in the plan area; therefore, no indirect or cumulative impacts are expected.

The remaining 15 species occur within 7 habitat guilds as follows:

- Grasslands – 2 species
- Meadows – 2 species
- Mesic forests – 6 species

- Rocky habitats – 1 species
- Subalpine forests – 1 species
- Transitional habitats – 4 species
- Wetlands – 5 species

Some species occur in more than one guild.

The habitat and stressors for these sensitive species, as well as the effects of the action alternatives, would be similar to those disclosed for the species of conservation concern within each habitat guild. The protections provided by plan components to plant species of conservation concern and their habitats described above would also help protect sensitive plant species and communities that occupy these types of habitats. Thus, habitat would be maintained in the plan area for all species and threats are not considered to pose a risk to the viability of these species in the plan area. As new information becomes available or additional threats become known, these species or others would be reconsidered for species of conservation concern designation.

Determination: May impact individuals but would not contribute toward a trend for federal listing or loss of viability.

3.2.3 Climate Change and Forest Carbon

Climate change is a particularly complex challenge given its global nature and inherent interrelationships among its sources, causes, mechanisms of action, and impacts. The effects of climate change observed to date and projected to occur in the future include changes in temperature, precipitation, and disturbance patterns that drive and stress ecosystems and the benefits they provide, including degraded air quality, water resources, wildlife, carbon storage, and the quality of recreational experiences.

This analysis considers the potential impacts of climate change on the Nez Perce-Clearwater National Forests, as indicated by consideration of changes in climate, such as temperature and precipitation patterns, and the effects of climate change impacts on ecological, social, and economic resources. Land Management Plans are strategic documents and do not authorize or mandate a specific agency action. Therefore, a qualitative, programmatic approach was used in the analysis and no quantitative estimate of climate impacts resulting from the Land Management Plan was conducted. This section also considers the potential effects of the proposed alternatives on forest carbon, as indicated by consideration of changes in carbon sequestration and storage arising from natural and management driven processes.

Climate Change

Climate change impacts to the environment are interwoven with the social, political, and economic fluctuations occurring at local, national, and world scales. Climate is described by the long-term characteristics of precipitation, temperature, wind, snowfall, and other measures of weather that occur over a long period in a particular place (Halofsky, Peterson, et al. 2018a, b) and is a primary driver of the ecosystem. The Nez Perce-Clearwater lies at the boundary between the warm, wet maritime airflows from the Pacific Ocean and the cooler, drier airflows from Canada. Summers are typically hot and dry, and winters are relatively cold. Precipitation varies seasonally, with little occurring during the summer months. The average annual precipitation ranges from 20 inches in low elevation valleys to 60 to 80 inches at the upper elevations. The majority of precipitation falls as snow between October and April.

Historic trends in climate are correlated to changes in ecosystem components. Therefore, future climate is an important component of the effect’s analyses for Land Management Plan. Natural climate cycles have occurred historically and will continue into the future. Human activities, such as fuel burning, industrial activities, land-use change, animal husbandry, and agriculture, lead to increases in ambient greenhouse gases, which contribute to the "greenhouse effect" (Melillo et al. 2014). The Intergovernmental Panel on Climate Change (IPCC) states human influence on the climate system is clear, and recent anthropogenic emissions of greenhouse gases are the highest in history (Intergovernmental Panel on Climate Change 2007). Warming temperatures are the most certain consequence of increased carbon dioxide in the atmosphere (Halofsky, Peterson, et al. 2018a, b). Understanding and responding to climate change will play a critical role in the future of land management and the ability of the Nez Perce-Clearwater to continue to provide a range of values and benefits. The current 1987 Forest Plans do not address climate change.

This section provides a broad overview of climate conditions for the Nez Perce-Clearwater. Each resource section of the Final Environmental Impact Statement may address more specific impacts of climate change where relevant.

Relevant Laws, Regulations, and Policy

Executive Orders

Executive Order 14008 of January 27, 2021, Tackling the Climate Crisis at Home and Abroad: provides direction for a government-wide approach to combat the climate crisis. The order requires a coordinated approach from planning to implementation coupled with substantive engagement by stakeholders, including state, local, and tribal governments. The order also emphasizes environmental justice for historically marginalized communities, including low-income, minority, Indigenous, and other overburdened and underserved communities that could be disproportionately affected by climate change.

Agency Regulations

36 CFR 219.8: requires a plan to include plan components to maintain or restore structure, function, composition, and connectivity of terrestrial and aquatic ecosystems and watersheds, taking into account stressors, such as climate change (36 CFR 219.8(a)).

36 CFR 219.12: states that the responsible official should consider measurable changes to the plan area related to climate change and other stressors affecting the plan area when developing a monitoring program for the plan area (36 CFR 219.12(a)(5)(v)).

Policy

FSM 1920, Section 1921.02: states that an objective of land management planning is to improve the resilience of National Forests and Grasslands to climate change and other stressors.

FSH 1909.12, Chapter 20, Section 23: refers to requirements for considering and addressing climate and climate change when developing plan components for ecological sustainability and diversity of plant and animal communities.

FSH 1909.12, Chapter 30: contains direction for considering and addressing climate change when developing the plan monitoring program.

Other Guidance

USDA Action Plan for Climate Adaptation and Resilience: response to Executive Order 14008, outlining how the U.S. Department of Agriculture (USDA) will provide relevant information, tools, and resources to its stakeholders and target programs and activities to increase resilience to climate impacts (U.S. Department of Agriculture 2021).

USDA Forest Service Climate Adaptation Plan FS-1196: presents a comprehensive approach to integrating climate change adaptation into the Forest Service's operations and mission. The plan outlines key climate risks to the agency's operations and critical adaptation actions to reduce these risks and help ensure the Forest Service continues to meet the needs of present and future generations (U.S. Department of Agriculture 2022b).

Council on Environmental Quality, National Environmental Policy Act Guidance on Consideration of Greenhouse Gas Emissions and Climate Change (Federal Register Doc. 2023–00158): interim guidance to assist agencies in analyzing greenhouse gas and climate change effects of their proposed actions under the National Environmental Policy Act.

Secretary's Memorandum 1077-004, Climate Resilience and Carbon Stewardship of America's National Forests and Grasslands: outlines actions that the Department and USFS will undertake so that data-informed policies, strategies, and actions are in place to provide for increased carbon stewardship and climate resilience across our national forests and grasslands.

Best Available Scientific Information

An ever-increasing body of knowledge exists regarding climate and climate change. This climate change summary is based in large part upon the work of the Northern Rockies Adaptation Partnership, which is a "science-management" collaboration with the goals of 1) assessing vulnerability of natural resources and ecosystem services to climate change and 2) developing science-based adaptation strategies that can be used by national forests to understand and mitigate the negative effects of climate change. The Northern Rockies region includes the U.S. Forest Service Northern Region and the adjacent Greater Yellowstone area, spanning across northern Idaho, Montana, northwest Wyoming, North Dakota, and South Dakota. Five subregions are identified and assessed; the Nez Perce-Clearwater is in the Western Rockies subregion. The Climate Change Vulnerability and Adaptation in the Northern Rocky Mountains: Part 1 and Part 2 (Halofsky, Peterson, et al. 2018a, b) documents summarize climate projections, modelling results, peer-reviewed literature, and other information on climate change relevant to the Northern Rockies area. Climate change vulnerability assessments draw largely on available information, including from existing models and spatial data, primary scientific literature, and other larger scale climate impact assessments. Nez Perce-Clearwater specific documents, such as A Climate Change Vulnerability Assessment for Resources of Nez Perce-Clearwater National Forests (EcoAdapt 2014), Climate Change Adaptation Strategies for Resources of the Nez Perce-Clearwater National Forests (EcoAdapt 2015), and the Nez Perce-Clearwater National Forests Forest Plan Assessment - Socioeconomic Climate Change Vulnerability Assessment (U.S. Department of Agriculture 2014e) also offer useful information.

Global climate models are the principal source of future climate projections and are effective at simulating global climate characteristics; however, because the spatial patterns of regional climate are far more heterogeneous than suggested by global climate model outputs, specific downscaling techniques are used to provide inputs for regional and sub-regional analyses (Daniels et al. 2012). The Northern Rockies Adaptation Partnership compiled downscaled climate information to a sub-regional level, which is a scale that is meaningful for the Nez Perce-Clearwater and its surrounding landscapes.

The Coupled Model Intercomparison Project (CMIP) began in 1995 to coordinate a common set of experiments for evaluating changes to past and future global climate, allowing comparison of results from different global climate models around the world (Halofsky, Peterson, et al. 2018a, b). CMIP Version 3 simulations with emissions scenarios from the Special Report on Emissions Scenarios which represent futures with different combinations of global population growth and policies. Conversely, CMIP Version 5 simulations are driven by "representative concentration pathways," which do not define emissions but rather concentrations of greenhouse gases and other agents that influence the climate and do not consider climate policy actions (Halofsky, Peterson, et al. 2018a, b). The Northern Rockies Adaptation Partnership considered CMIP Version 5 climate scenarios but also used the best available information from multiple literature sources, some of which are based upon CMIP Version 3 modeling results.

Climate projections embody several uncertainties, including the uncertainty of future emissions driven by socioeconomic processes and unpredictable policy choices, the variability internal to a given global climate model's simulation of weather and climate, the variability related to parameterization and other model characteristics, and the uncertainty or error in observed climate data used in downscaling global climate model output (Daniels et al. 2012).

Current Climate and Recent Historical Trend

The climate of the Northern Region fluctuates between cool and warm periods and is affected by multiple factors. The influences of sea surface temperature and atmospheric pressure are thought to directly influence drought in the western United States (Kitzberger et al. 2007). Multiple indices exist to measure sea surface temperatures, including the Pacific Decadal Oscillation, which tracks variations in the northern Pacific Ocean that tend to cycle every 20 years (Zhang et al. 1997). Correlations between these variations and ecological disturbances, such as wildfire, have been shown. Also, in the northern Rocky Mountains, the majority of the variability in peak and total annual snowpack and streamflow is explained by season-dependent interannual-to-interdecadal changes in atmospheric circulation associated with Pacific sea temperatures (Pederson et al. 2010).

Recent climate cycles can be demonstrated by variations in the Pacific Decadal Oscillation (Joint Institute for the Study of the Atmosphere and Ocean 2017), as shown in Figure 26. The early 1900s were a relatively normalized period where warm and cool years were relatively equally represented and fluctuations low. The following period until the 1940s was dominated by warm conditions, while the period from about 1950 to 1980 was dominated by cool conditions. During this cool period, ecological disturbances, such as wildfire, affected a relatively small area, although this was also influenced by human actions, such as fire suppression and livestock grazing. Since the 1980s, the Northern Region and the Nez Perce-Clearwater have experienced a warm Pacific Decadal Oscillation cycle, along with increased extent and frequency of disturbances including wildfire and insect outbreaks.

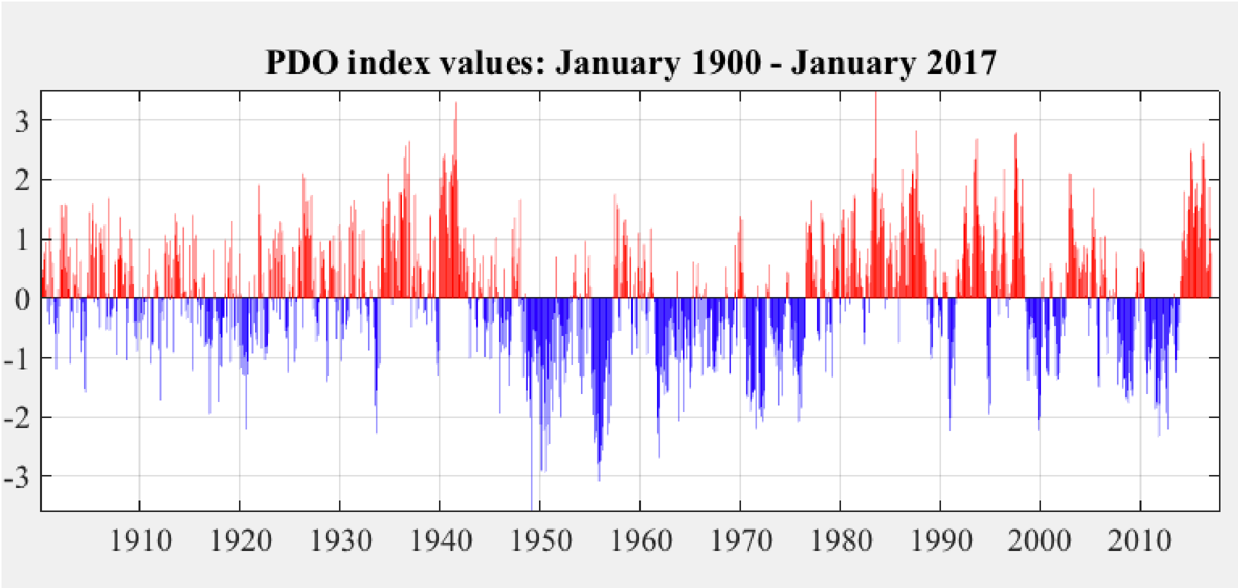

Figure 26. Pacific Decadal Oscillation index values from 1900 to 2017.

Data Source: Source: Joint Institute for the Study of the Atmosphere and Ocean, http://research.jisao.washington.edu/pdo/

Other climate data demonstrates trends for temperature and precipitation over the recent historical period. In the Western Rockies subregion, the Northern Rockies Adaptation Partnership found that from 1895 to 2012, the annual mean monthly minimum temperature increased by about 3.0 degrees Fahrenheit, while the annual mean monthly maximum temperature increased by about 0.6 degrees Fahrenheit. During the same period, the annual mean monthly precipitation increased slightly by an average of about 0.1 inch per month (Halofsky, Peterson, et al. 2018a, b). Current climate conditions in this subregion include an annual mean monthly maximum temperature of approximately 53 degrees Fahrenheit; an annual mean monthly minimum temperature between 27 and 33 degrees Fahrenheit; and an annual precipitation between 35 and 40 inches (Halofsky, Peterson, et al. 2018a, b).

Future Climate and Expected Impacts

The future climate has the potential to influence all resources. Natural variation in climate will continue, coupled with the effects of anthropogenic influences. Different climate models project differing rates of change in temperature and precipitation because they operate at different scales, have different climate sensitivities, and incorporate feedbacks differently. However, the climate models are unanimous in projecting increasing average annual temperatures over the coming decades. As noted in Climate Change Vulnerability and Adaptation in the Northern Rocky Mountains: Part 1 and Part 2 (Halofsky, Peterson, et al. 2018a, b):

"Global climate models project that the Earth's current warming trend will continue throughout the 21st century in the Northern Rockies. Compared to observed historical temperature, average warming across the five NRAP subregions is projected to be about 4 to 5 °F by 2050, depending on greenhouse gas emissions. Precipitation may increase slightly in the winter, although the magnitude is uncertain. Climatic extremes are difficult to project, but they will probably be more common, driving biophysical changes in terrestrial and aquatic ecosystems. Droughts of increasing frequency and magnitude are expected in the future, promoting an increase in wildfire, insect outbreaks, and non-native species. These periodic disturbances, will rapidly alter productivity and structure of vegetation, potentially altering the distribution and abundance of dominant plant species and animal habitat."

Projected climate changes in the Western Rockies subregion (Halofsky, Peterson, et al. 2018a, b), which includes the Nez Perce-Clearwater, include:

- Changes in the climate affecting the mountain snowpack will have important hydrologic implications. Most of the streams in the Western Rockies subregion depend on snowmelt for runoff, and snowpack changes strongly dictate streamflow responses.
- Temperature is projected to increase 5 to 10 degrees Fahrenheit by 2100, including increases in both the annual mean monthly minimum and annual mean monthly maximum.
- Mean monthly maximum and minimum temperatures are projected to increase for all seasons. The mean monthly spring and fall minimum temperature and the mean monthly winter maximum temperature may rise above freezing.
- Seasonal precipitation is projected to be slightly higher in winter and spring and slightly lower in summer than during the historical period of record.

The influence of future climate spans across all resources. Climate change is addressed in further detail in many of the resource sections in the Final Environmental Impact Statement. The following examples of resource specific climate change projections are a summary from Halofsky et al. (2018a, b) and other sources as noted:

- Decreasing snowpack and declining summer flows will alter timing and availability of water supply.
- Declining summer low flows will affect water availability during late summer.
- Decreased snowpack, in combination with higher air temperature and increased wildfire, will increase stream temperatures and reduce the vigor of cold-water fish species.
- Declining summer water flows may result in some communities experiencing summer water shortages. Water quality will decrease in some locations if wildfires and floods increase.
- Increasing air temperature will influence soil moisture and will cause gradual changes in the abundance and distribution of tree, shrub, and grass species, with more drought tolerant species becoming more competitive. The earliest changes will be at ecotones.
- Natural disturbance will be the primary facilitator of vegetation change, and future forest landscapes may be dominated by younger age classes and smaller trees.
- High-elevation forests will be especially vulnerable if disturbance frequency increases significantly.
- As wildfires and insect outbreaks become more common, the supply of timber and other forest products could become less reliable.
- A longer growing season will increase productivity of rangeland types and, thus, available forage for livestock, especially those dominated by grasses.
- In montane grasslands, wildfire may kill Douglas-fir and other species that have been recently established through fire exclusion.
- High-elevation, snowy environments provide habitat for predators, such as the Canada lynx, fisher, and wolverine. Predator prey of snowshoe hare is expected to deteriorate as snowpack decreases.
- Animal species that are mobile or respond well to disturbance and habitat patchiness, such as deer and elk, will be resilient to a warmer climate.
- Some amphibian species may be affected by pathogens that are favored by a warmer climate.

- A warmer climate will generally improve opportunities for warm-weather recreation, such as hiking, camping, and sightseeing, because it will create a longer time during which these activities are possible.
- A warmer climate will reduce opportunities for snow-based winter activities, such as downhill skiing, cross-country skiing, and snowmobiling, because snowpack is expected to decline.
- Recreationists may seek more water-based activities to seek refuge from hotter summer weather.
- Viewsheds and air quality will be negatively affected by more wildfires and longer pollen seasons.
- Regulation of soil erosion will be decreased by agricultural expansion, spread of non-native plants, and increased frequency of wildfire and floods.
- Carbon sequestration will be increasingly difficult if disturbances increase as expected.
- Climate-induced changes in habitats will affect the abundance of culturally valued plants and animals.
- Studies by Westerling (2016) and Morgan et al. (2008) identify the mid-elevational areas located between 5,000 to 7,500 feet in the Northern Rockies as having the greatest risk of climate-induced fire increases in the region and have also found that the timing of spring snow-melt can drive the intensity of fires.
- Hotter and drier weather and earlier snowmelt mean that western wildfires start earlier in the spring, last later into the fall, and burn more acreage (Melillo et al. 2014).
- Changes in the timing of streamflow related to changing snowmelt are already observed and will continue, reducing the supply of water for many competing demands and causing far-reaching ecological and socioeconomic consequences (Mote et al. 2014).
- The combined impacts of increasing wildfire, insect outbreaks, and tree diseases are already causing widespread tree die-off and are virtually certain to cause additional forest mortality by the 2040s and long-term transformation of forest landscapes. Under higher emissions scenarios, extensive conversion of subalpine forests to other forest types is projected by the 2080s (Mote et al. 2014).
- Changing climate is likely to increase the risks of and extent of invasive species. Controlling weeds costs the United States more than 11 billion dollars per year, with most of that spent on herbicides (Hatfield et al. 2014). Both herbicide use and costs are expected to increase as temperatures and carbon dioxide levels rise (Hatfield et al. 2014).

Management Strategies that Address Climate Change

In the broadest terms, natural resource management strategies for addressing climate change can be classified under adaptation and mitigation. Adaptation refers to all approaches taken to adjust, prepare for, and accommodate new conditions that are created by changing climates. Mitigation in the context of climate change is an intervention designed to reduce the human influence on the climate system, primarily through increased removal of greenhouse gases from the atmosphere and the reduction of greenhouse gas emissions. In natural resources, this may include managing forests in a way that sequesters and stores more carbon dioxide. Adaptation and mitigation are often parallel strategies that can be simultaneously integrated into natural resource management. Ecosystems that are better adapted to future climates will be better able to hold on to their stores of carbon and avoid releasing them into the atmosphere. A range of adaptation options exist for managing forests to be better able to cope with the negative effects of climate change, including resistance, resilience, and transition strategies.

Resistance - This set of options promotes resistance to the effects of climate change and focuses on improving the defenses of the Nez Perce-Clearwater against anticipated changes or directly defending the system against disturbance so that the system remains unchanged. A resistance strategy may be appropriate for defending a high-risk or high-value resource in the short-term; for example, creating an in-situ refuge for a critically vulnerable endangered species or constructing fire breaks where a resource is threatened by near-term fire risk. It may also make sense to pursue resistance where microclimates may buffer anticipated climate changes. Resistance options are often expensive and take a considerable amount of time and resources since they are focused on keeping changes at bay. In addition, they can be risky; in some situations, conditions will eventually become so different that a resource passes a threshold and resistance becomes futile. Thus, choosing to resist change and maintain a system in its present condition will not be appropriate in all situations and may become less appropriate over time as external pressures mount.

Resilience - Resilience options accommodate gradual change, usually returning to a prior condition after disturbance or seeking to maintain status quo, even in the face of forces of change. Climate change may lead to new intensities of stressors and extreme events. Management options that improve the ability of a resource to return to or maintain a desired condition after encountering stressors fall under the category of resilience. Healthy species, forests, and ecosystems are considered more resilient to change and many resilience strategies are aimed at creating healthy forests. For example, using a combination of mechanical thinning and prescribed burning in a dense forest threatened by risk of wildfire could reduce the intensity of future fires, allowing the national forest to more easily withstand and regenerate after burning. In the case of endangered or threatened species, reducing harvesting or other non-climate stresses on the species could make the population more resilient to climate change influences. As with resistance options, strategies to promote resilience may only be successful in the relatively short-term in many areas; eventually, climate changes may be too drastic to allow a return to a prior condition.

Transition - Transition options intentionally accommodate change and enable ecosystems to adaptively respond to future conditions. By encouraging a gradual and intentional transition, it may be easier to maintain important functions and values over time, even as the character or a system changes. In certain locations or over longer time scales, it may be difficult for a system to either resist change or return to a prior condition after disturbance. Where this is the case, managers can adopt strategies to help these systems transition smoothly to a future state that maintains ecosystem processes and functions that are considered beneficial. An example would be intentionally increasing tree species diversity on a forested landscape following a disturbance event. A diverse pool of tree species would increase the candidates available for selection under new climate conditions and would reduce opportunities for mass die-offs, such as from pest outbreaks. Promoting connected landscapes to allow species to more easily colonize new environments would be another example of a transition approach. In each of these situations, it is recognized that future landscapes may not be the same as they were historically, but they will ideally maintain certain desired features, such as forested habitat and watershed protection.

A complementary adaptation framework (Schmitz and Trainor 2014) outlines six adaptation approaches considered at three ecological levels—species and population, ecosystem, and landscape scale. The adaptation approaches include protecting current patterns of biodiversity; large, intact, natural landscapes and ecological processes; and the geophysical setting. The adaptation approaches also promote maintaining and restoring ecological connectivity and identifying and managing climate refugia and areas that could provide for species expected to be displaced by climate change.

In forest management, examples of mitigation actions can generally be placed into three categories: emissions avoidance, sequestration, and substitution. Emissions avoidance focuses on maintaining existing carbon storage in trees by avoiding deforestation and reducing potential impacts from catastrophic disturbances, such as wildfire. Through the National Roadmap for Responding to Climate change program (U.S. Department of Agriculture 2011b), the Forest Service actively focuses on reducing emissions by soundly managing vehicles and equipment, promoting telework opportunities to lessen employee commuting, and reducing energy use in buildings. Enhancing sequestration encompasses actions, such as afforestation (planting trees) and managing forests to increase the amount of carbon stored relative to “business as usual.” Substitution describes actions that reduce greenhouse gas emissions by using forest products in the place of fossil fuel intensive products. This would include using renewable forest-derived biofuels for energy instead of fossil fuels and using wood that will store carbon long-term, such as lumber for wood houses, in place of materials that may be more energy-intensive to produce.

In response to government, business, and individual commitments to reduce carbon dioxide emissions, carbon is now a priced environmental commodity in the global marketplace. The United States carbon market is in its formative stages. States and regions are developing climate change strategies and policy for reducing carbon dioxide emissions, and mandatory markets are forming at the regional and state levels. The Voluntary Reporting of Greenhouse Gases Program, established by Section 1605(b) of the Energy Policy Act of 1992, provides a means for organizations and individuals, including forest landowners and other land managers, to record their baseline emissions and emission reductions. The Forest Service’s National Roadmap for Responding to Climate Change (U.S. Department of Agriculture 2011b) outlines the assessment and management of carbon as a mitigation strategy for national forests and identifies a variety of tools and models to evaluate carbon stocks.

Forest Service Climate Adaptation Plan

The U.S. Department of Agriculture (USDA) Forest Service Climate Adaptation Plan, released in 2022, presents a vision for integrating climate change adaptation into the Forest Service’s operations and mission. The plan is part of the Forest Service’s response to Executive Order 14008: Tackling the Climate Crisis at Home and Abroad, which calls on Federal Departments and agencies to develop climate adaptation plans that secure environmental justice and spur economic opportunity. In October 2021, the USDA released its Action Plan for Climate Adaptation and Resilience (U.S. Department of Agriculture 2021) to describe how the USDA is preparing for and responding to current and future impacts of climate change. As part of developing its plan, USDA issued a new departmental regulation (DR 1070-001), directing each of its agencies to update its adaptation plans. The USDA Forest Service Climate Adaptation Plan describes the top risks to the agency’s mission, responsibilities, and operations and outlines key actions to manage these risks (U.S. Department of Agriculture 2022b). The adaptation plan builds on the modes of action outlined in the Forest Service’s National Roadmap for Responding to Climate Change (U.S. Department of Agriculture 2011b) and aligns with other department and agency policies, strategy documents, and initiatives at the interface of climate change, sustainability, and environmental justice (U.S. Department of Agriculture 2022b).

The Forest Service identified six key climate-related vulnerabilities in the adaptation plan that affect the agency’s mission as outlined in Table 94. To reduce these risks, the Forest Service identified six overarching adaptation actions that correspond to the six risk categories (Table 94).

Table 94. Climate-related vulnerabilities and adaption actions identified in the Forest Service Climate Adaptation Plan

Climate-related vulnerabilities	Adaptation Actions
Shifting fire regimes and resulting effects on ecological integrity, multiple uses, human safety and well-being, and wildland fire management operations.	Adapt to changing fire regimes.

Climate-related vulnerabilities	Adaptation Actions
Extreme events and disturbances, including the effects of flooding, drought, insect outbreaks, invasive species, and severe storms.	Prepare ecosystems and watersheds for extreme events and intensifying disturbances.
Chronic stressors to watersheds and ecosystems, such as altered productivity and composition, changes in habitat for plants and animals, and implications for the agency's ability to manage these systems over time.	Sustain and improve ecosystem and watershed function in the face of chronic stressors.
Disruption in the delivery of ecosystem products and services, including clean water, carbon uptake and storage, forest and rangeland products, and recreation opportunities.	Support the delivery of ecosystem products and services in a changing climate.
Disproportionate impacts on disadvantaged communities and Tribal Nations, including human health impacts, loss of cultural resources, and threats to economic prosperity and equity.	Deliver environmental justice through adaptation actions.
Threats to the agency mission, infrastructure, and operations from disruption to operations, strains on workforce capacity, more complex public engagement, and fewer resources.	Increase agency capacity to respond to climate change.

Data Source: USDA Forest Service Climate Adaptation Plan (U.S. Department of Agriculture 2022b).

The Land Management Plan includes management direction that directly aligns with the adaptation actions outlined in the Forest Service Climate Adaptation Plan. Plan components in the Forestlands and Fire Management sections promote adaptation to changing fire regimes by increasing the use of planned and unplanned ignitions and thinning treatments that help reduce near-term wildfire risks and allow landscapes to accommodate beneficial fire. Additionally, there are proposed desired conditions and objectives for vegetation treatments to improve the composition, structure, function, and connectivity of forested ecosystems, which can also help forests adapt to changing climates. The Terrestrial Ecosystems, Aquatics Ecosystems, and Infrastructure sections include plan components that support maintaining or improving ecological integrity, as well as upgrading the road system to better withstand disturbances. These efforts help to prepare ecosystems and watersheds for extreme events and intensifying disturbances and sustain and improve ecosystem and watershed function in the face of chronic stressors. Implementation of plan components in the Forestlands, Aquatic Ecosystems, Municipal Watershed, Livestock Grazing, and Recreation sections would help support the delivery of ecosystem products and services in a changing climate. The Tribal Trust Responsibilities, Aquatic Ecosystems, and Infrastructure sections include plan components that promote the provision of resources and continued access to underserved communities. Goals in many of the resource sections emphasize working with federal, state, and county agencies, tribes, and other partners, which could help with increasing the capacity to respond to climate change.

Land Management Plan Components that Address Climate Change

The 2012 Planning Rule (U.S. Department of Agriculture 2012c) specifies that "land management plans must include plan components, including standards or guidelines, to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity, taking into account…stressors, such as climate change" (219.8 (a)(1)(iv). Although not specifically mentioned, most of the physical and biological ecosystem desired conditions in the Land Management Plan were developed to facilitate natural ecological processes and create healthy ecosystems, which are more resilient and better adapted to changing climate. The following plan components explicitly address climate change and promote resilience and adaption to the effects of climate change:

- FW-DC-TE-01. Uncommon habitat elements (mineral licks, talus slopes, fractured wet bedrock, rocky outcrops, scree slopes, waterfalls, and geologic inclusions) support long-term persistence of endemic species with narrow or vary narrow habitat specificity and limited distribution associated with these habitats.
- FW-DC-TE-03. Plant communities are comprised of a diverse mix of native grass, forb, shrub, and tree species, which provide forage for pollinator species.
- Forestlands Desired Conditions. The Forestlands Desired Conditions were developed to promote and increase the resiliency of forest landscapes and incorporate adaptation to changing climates.
- FW-DC-FIRE-01. Restore and maintain landscapes: Landscapes across the Nez Perce-Clearwater are resilient to fire-related disturbances in accordance with management objectives. Natural fuel conditions emulate the structure, species mix, spatial pattern, extent, and resiliency of the historic fire regime of the area. Wildland fires burn with a range of intensity, severity, and frequency that allows ecosystems to function in a healthy and sustainable manner and meet desired conditions for other resources.
- FW-DC-SOIL-01. Soil productivity and function contribute to the long-term resilience of ecosystems.
- FW-DC-WTR-01. National Forest System lands provide the distribution, diversity, and complexity of watershed and landscape-scale features including natural disturbance regimes and the aquatic and riparian ecosystems to which species, populations, and communities are uniquely adapted. Watersheds and associated aquatic ecosystems retain their inherent resilience to respond and adjust to disturbances, including climate change, without long-term, adverse changes to their physical or biological integrity.
- FW-DC-WL-02. Ecological conditions on the Nez Perce-Clearwater contribute sustainable habitat to maintain species of conservation concern. Habitat is resilient and adaptable to stressors and likely future environments.
- GA-DC-SR-02. Habitat for Ponderosa pine associated species, including legacy trees and snags, are within desired conditions within Ponderosa pine systems (See FW-DC-FOR-02, FW-DC-FOR-03, FW-DC-FOR-04, and FW-DC-FOR-05). Understory characteristics do not facilitate stand replacing fires and are composed of native plants that provide insect populations as forage for Ponderosa pine associated species. These habitats are resilient to changes due to climate change.FW-DC-ARINF-02. The transportation network is resilient to the effects of climate change, including the ability to accommodate increased runoff and peak flows that may exceed historic streamflow events.

Strategies included in the Land Management Plan focus on promoting resilience to change, creating resistance to change, and enabling forests to respond to change (Millar et al. 2007). The Northern Rockies Adaptation Partnership publication Halofsky et al. (2018a, b) is a principal source of information for identifying resource vulnerabilities and providing strategies and approaches to address vulnerabilities specific to the Northern Rockies. Appendix G provides further information on climate change adaptation strategies and identifies plan components from the Land Management Plan that support them. The Land Management Plan also includes a monitoring plan (Appendix 3) with climate change specific elements, and a potential management approach for climate change (Appendix 4) that offers possible strategies that may be used to implement plan direction.

Forest Carbon

Global atmospheric concentrations of carbon dioxide, methane and nitrous oxide have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years (Intergovernmental Panel on Climate Change 2013). The global increases in carbon dioxide concentration are due primarily to fossil fuel use and land use change, while those of methane and nitrous oxide are primarily due to agriculture. Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level. Most of the observed increase in global average temperatures since the mid-20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations (Intergovernmental Panel on Climate Change 2013).

Forests are dynamic systems that naturally undergo ebbs and flows in carbon storage and emissions as trees establish and grow, die with age or disturbances, and re-establish and regrow. Through photosynthesis, growing plants remove carbon dioxide from the atmosphere and store it in forest biomass, such as in plant stems, branches, foliage, and roots. Some of this organic material is eventually stored in forest soils through biotic and abiotic processes (Ryan et al. 2010). Carbon can also be transferred and stored outside of the forest ecosystem in the form of wood products, further influencing the amount of carbon entering the atmosphere (Gustavsson et al. 2006, Skog et al. 2014). Many management activities initially remove carbon from the forest ecosystem, but they can also result in long-term maintenance or increase in forest carbon uptake and storage by improving forest health and resilience to various types of stressors (McKinley et al. 2011).

Changes between Draft and Final Environmental Impact Statement

Comments received since the proposed action and draft environmental impact statement were published have been used where appropriate to improve the Land Management Plan and have helped inform this Final Environmental Impact Statement. An updated baseline carbon assessment was conducted, using new available tools from the Forest Service Office of Sustainability and Climate and has been included in Appendix D. Although the report has been updated, it draws upon many of the same data and literature sources described in the Draft Environmental Impact Statement. Multiple minor changes were made for the Final Environmental Impact Statement; all changes are within the scope of the Draft Environmental Impact Statement analysis and address issues that the public had an opportunity to comment on. As a result of public input, an additional alternative was developed called the Preferred Alternative. Analysis of the Preferred Alternative for forest carbon is similar to the other action alternatives.

Relevant Laws, Regulations, and Policy

There are no applicable legal or regulatory requirements or established thresholds concerning management of forest carbon or greenhouse gas emissions. The 2012 Planning Rule (U.S. Department of Agriculture 2012c) and associated directives require an assessment of baseline carbon stocks and a consideration of this information in management of the national forests.

Methodology

The spatial scale of this analysis includes the forested lands of the plan area. The Nez Perce-Clearwater National Forests consist of approximately 4 million acres, with about 3.7 million acres as forested lands. The effects analysis for greenhouse gas emissions is the global atmosphere given the mix of atmospheric gases can have no bounds. The temporal scale for analyzing carbon stocks and emissions focuses on the expected 15-year lifespan of the plan. This report includes analysis and discussion beyond this expected lifespan to provide context for potential forest carbon dynamics and factors influencing these dynamics in the future. However, estimates of future carbon stocks and their trajectory over time remain unclear because of uncertainty from the multiple interacting factors that influence carbon dynamics.

Analysis Methods and Assumptions

The affected environment section summarizes the Forest Carbon Assessment for the Nez Perce-Clearwater National Forests (Hoang et al. 2019), which is included in Appendix D. The carbon assessment draws largely from two recent U.S. Forest Service reports: the Baseline Report (U.S. Department of Agriculture 2015a) and the Disturbance Report (Birdsey et al. 2019). These reports provide assessments of forest ecosystem and harvested wood product carbon stocks and flux, and the factors that have influenced carbon dynamics. The Resource Planning Act assessment (U.S. Department of Agriculture 2016b) and a regional vulnerability assessment (Halofsky, Peterson, et al. 2018a, b) also provide information on potential future carbon conditions. These reports incorporate advances in data and analytical methods and collectively represent the best and most relevant scientific information available for the Nez Perce-Clearwater.

Potential carbon effects are discussed qualitatively, with supporting estimates where possible. This is accomplished by drawing on the quantitative analysis of the impacts of past management activities on forest carbon stocks and fluxes, as well as through future-looking analysis where available (Hoang et al. 2019).

The following information may be useful in understanding the analysis:

- 1 Hectare (ha) = 2.471 acres
- 1 Teragram carbon (Tg C) = 1,000,000 Megagram carbon (Mg C)
- 1 Megagram carbon (Mg C) = 1 tonne carbon = 1.1023 short tons (U.S.) carbon
- 1 General Sherman Sequoia tree = 1,200 Megagram carbon (Mg C) stored
- 1 Megagram carbon (Mg C) mass = 1 tonne carbon mass = 3.67 tonnes carbon dioxide
- A typical passenger vehicle emits about 4.6 tonnes carbon dioxide per year

Measurement Indicators

The key indicators for carbon sequestration include:

- Carbon pools or carbon stocks, carbon uptake, and carbon dioxide emissions, and
- Natural and human-caused influences on carbon stocks, uptake, and emissions.

Affected Environment

The carbon legacy of the Nez Perce-Clearwater is tied to the history of Euro-American settlement, land management, and disturbances. Human activities associated with settlement, such as mining, logging, and grazing, began in the mid-to-late 1800s. Historical disturbance dynamics, forest regrowth and recovery, and forest aging have been most responsible in driving carbon accumulation trends since the early 1900s.

Wildfire is the most influential disturbance on the Nez Perce-Clearwater. On average, 315,000 acres of large fires (greater than 1,000 acres) burned per decade from 1870 to 2019 (Figure 31). The dominant, historical fire regime that occurred within forested vegetation in the Inland Empire (that is, an area of the Pacific Northwest that includes parts of Washington, Oregon, Idaho, and Montana) can be characterized as a variable or mixed-severity fire regime (Zack and Morgan 1994, Kilgore 1981, Brown 2000). The type of fire regime found within the Inland Empire commonly had a moderately short fire-return interval for nonlethal or mixed severity fires, with lethal crown fires occurring less often. Relative to the other two common fire regimes that are often recognized for forested vegetation—the nonlethal and stand-replacement regimes—the mixed-severity fire regimes are the most complex (Agee and Skinner 2005).

Individual mixed-severity fires typically leave a patchy pattern of mortality on the landscape, which creates highly diverse communities. These fires kill a large percentage of the more fire-susceptible tree species, such as hemlock, grand fir, subalpine fir, and lodgepole pine, and a smaller proportion of the fire-resistant species, including Western larch, Ponderosa pine, whitebark pine, and Western white pine (Arno et al. 2000). See the Fire Management section of the Final Environmental Impact Statement for further information regarding fire history on the Nez Perce-Clearwater.

Previous harvest activities within the project area set the stage for forest cover types to depart from historical species distributions. Harvest activities prior to the 1940s were associated with homesteading, mining, and railroad building. Since the early 1900s, harvest has impacted roughly 40 percent of the Nez Perce-Clearwater's landbase. From 1987 to 2018, the Nez Perce-Clearwater completed harvest activities on an average 13,200 acres per year. See the Forestlands section of the Final Environmental Impact Statement for further information regarding harvest history on the Nez Perce-Clearwater.

Carbon stock

Forests play an important role in regulating the global carbon cycle by taking up (sequestering) and storing carbon. Forests sequester carbon dioxide from the atmosphere through the process of photosynthesis and store this carbon in plant biomass. Over time, plant biomass carbon moves to other carbon pools in the forest and is eventually emitted back to the atmosphere through decomposition or combustion (fire). Forests are dynamic systems that naturally undergo ebbs and flows in carbon storage and emissions as trees establish and grow, die with age or disturbances, and re-establish and regrow. Carbon sequestration is the process by which plants take up atmospheric carbon dioxide and convert it to biomass. The rate of carbon sequestration is commonly measured as the net amount of carbon uptake in teragrams (Tg) per hectare per year. Once carbon is sequestered, it is held in the forest as a carbon stock, the amount of carbon stored at any one time. Carbon is stored in different reservoirs or zones, called carbon pools. Carbon stocks on the Nez Perce-Clearwater are contained in seven forest ecosystem carbon pools: above-ground live trees, below-ground live, understory, standing dead trees, down dead wood, forest floor, and soil (Figure 27). Carbon can also be transferred and stored in harvested wood products, such as lumber and furniture, and does not contribute to greenhouse gas emissions.

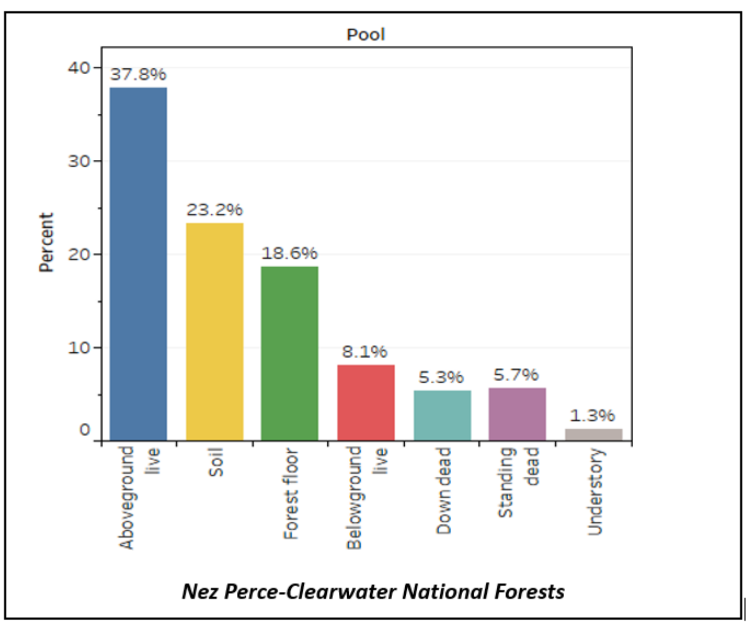

Figure 27. Percent carbon stocks in each of the forest carbon pools of the Nez Perce-Clearwater

Data Source: Nez Perce-Clearwater Carbon Dashboard Report (2019); estimated using the Carbon Calculation Tool (CCT). See the project record for more information.

Interest in terrestrial carbon sequestration has increased in an effort to explore opportunities for climate change mitigation. Carbon sequestration is the process by which atmospheric carbon dioxide is taken up by trees, grasses, and other plants through photosynthesis and stored as carbon in soils and biomass, such as trunks, branches, foliage, and roots. The sink of carbon sequestration in forests and wood products helps to offset sources of carbon dioxide to the atmosphere, such as deforestation, forest fires, and fossil fuel emissions.

Chapter 6 in Halofsky et al. (2018a) discusses the effects of climate change on forest vegetation in the Northern Rockies, providing the following information on carbon:

- Size and persistence of forest carbon sinks depend on land use, land management, and environmental factors, such as vegetation composition, structure, distribution, climate, and disturbance processes, including wildfire.
- Vegetated landscapes play an important role in storing carbon in the form of plant and animal materials (both live and dead), aboveground and in soils. Forests store carbon in soils (about 45 percent of total storage), aboveground and belowground live biomass (about 42 percent), dead wood (about 8 percent), and litter (about 5 percent) (Bonan 2008, Pan et al. 2011).
- Carbon typically accumulates in woody biomass and soils for decades to centuries until a disturbance event releases this stored carbon into the atmosphere (Goward et al. 2008). Disturbance is recognized as the primary mechanism that shifts ecosystems from carbon sinks to carbon sources (Baldocchi 2008). Wildfire in forested ecosystems is one of the primary disturbances that regulates patterns of carbon storage and release (Kasischke, O'Neill, et al. 2000, Kasischke, French, et al. 2000). Forest insect outbreaks can also release carbon through decomposition of needles and other fine fuels from attacked trees (Kurz et al. 2008).
- Although long intervals between disturbance events such as wildfires or insect outbreaks can allow carbon to accumulate for years to centuries, the probability of disturbance increases with time (Goward et al. 2008, Loehman et al. 2014). Thus, disturbance-prone forests will eventually move stored carbon to the atmosphere, regardless of management strategies designed to limit or prevent disturbance events.

According to results of the Baseline Report (U.S. Department of Agriculture 2015a), carbon stocks in the Nez Perce-Clearwater increased from 238.29 Tg C in 1990 to 279.43 Tg C in 2013, a 17.3 percent increase in carbon stocks over this period (Figure 28). Despite some uncertainty in estimates, there is a high degree of certainty that these carbon stocks have increased from 1990 to 2013. For context, 279 Tg C is approximately equivalent to the emissions from 223 million passenger vehicles in a year. The increase in storage indicates that the negative impacts caused by disturbance and recent climate conditions have been modest and offset by forest growth (Hoang et al. 2019).

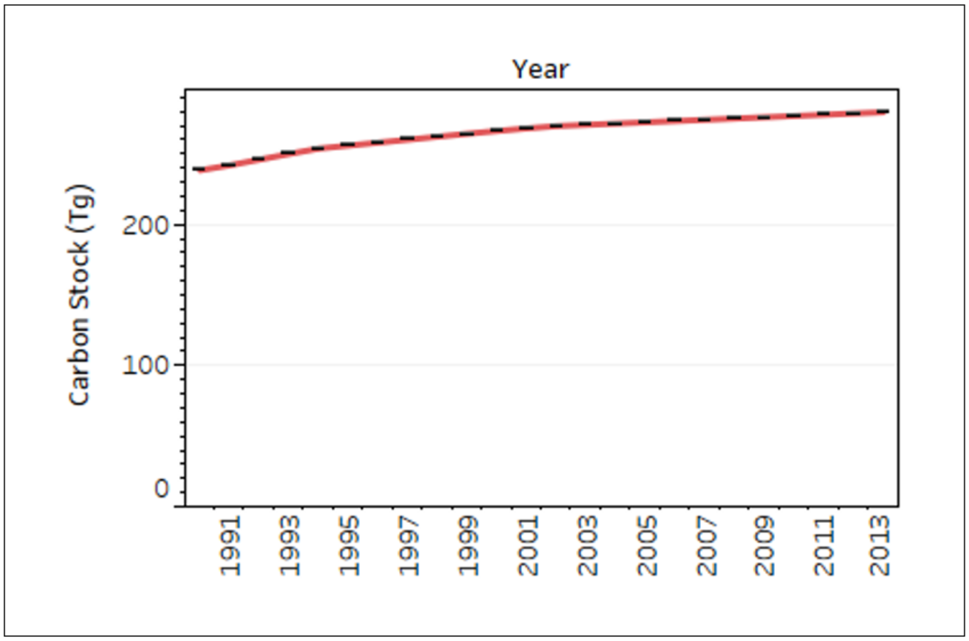

Figure 28. Total forest carbon stocks (in teragrams) from 1990 to 2013 for the Nez Perce-Clearwater.

Data Source: Nez Perce-Clearwater Carbon Dashboard Report (2019); estimated using the Carbon Calculation Tool (CCT). See the project record for more information.

Factors Influencing Forest Carbon

Stand Age

Stands regrow and recover at different rates depending on forest type and site conditions. Forests are generally most productive when they are young to middle age, then productivity peaks and declines or stabilizes as the forest canopy closes and as the stand experiences increased respiration and mortality of older trees (He et al. 2012, Pregitzer and Euskirchen 2004). Based on the 2019 Nez Perce-Clearwater Carbon Dashboard Report, over half of the stands on the Nez Perce-Clearwater are middle-aged and older (greater than 80 years. If the national forest continues on this aging trajectory, the pulse of middle-aged stands will reach a slower growth stage in coming years and decades, potentially causing the rate of carbon accumulation to decline. However, the pulse of young stands will also be moving into a maximum productivity stage, which may offset the declines in the middle-aged stands to a degree.

Disturbance

The ability of forests to store carbon is impacted by disturbances, such as wildfire, air pollution, insects and disease, and invasive plants. Fire and disease were the primary disturbances influencing carbon stocks on the Nez Perce-Clearwater from 1990 to 2011 (Table 94 and Figure 29). In 2011, the Nez Perce-Clearwater contained 2.52 Mg C per ha less non-soil carbon (that is, vegetation and associated pools) due to disease and 2.47 Mg C per ha less due to fire since 1990, as compared to a hypothetical undisturbed scenario. Harvest also played a disturbance role, contributing to 0.82 percent, approximately 12,282 hectares, of the average forested area on the Nez Perce-Clearwater from 1990 to 2011. Overall, harvest during the 21-year period resulted in a 0.37 percent loss of non-soil carbon (0.53 Mg C per hectare). Since the Nez Perce-Clearwater contained an average forested area of about 1,489,421 hectares during this period, non-soil carbon losses from harvest were about 37,590 Mg C per year (0.038 Tg C per year), compared to non-soil carbon losses from fire at 175,184 Mg C per year (0.175 Tg C per year).

Table 95. Estimated impact of disturbance to percent and hectares carbon stock by source of disturbance[1]

Indicator	Fire	Harvest	Insect	Disease	Combined
Percent of disturbance	5.38	0.82	0.56	n/a	6.76
Total estimated forested area disturbed (hectare)	80,143	12,282	8,328	n/a	100,752
Non-Soil carbon loss in 2011 (Mg C per hectare)	-2.47	-0.53	-0.01	-2.52	-5.33
Percent non-soil carbon loss in 2011	1.71%	0.37%	0.00%	1.74%	3.62%

[1]Calculations based on average forested area of 1,489,421 hectares.

Data Source: Nez Perce-Clearwater Carbon Dashboard Report (2019). See the project record for more information.

Although disturbance has played an important role for ecosystem integrity during this period, forest carbon losses associated with disturbances have been small compared to the total amount of carbon stored in the Nez Perce-Clearwater, resulting in a loss of about 3.6 percent of non-soil carbon from 1990 to 2011 from all disturbances, including fire, disease, insect, and harvest (Table 95). Given that the Nez Perce-Clearwater contained an average forested area of about 1,489,421 hectares during this period, non-soil carbon losses from all disturbances were about 378,029 Mg C per year (0.38 Tg C per year). For further information, see Appendix D.

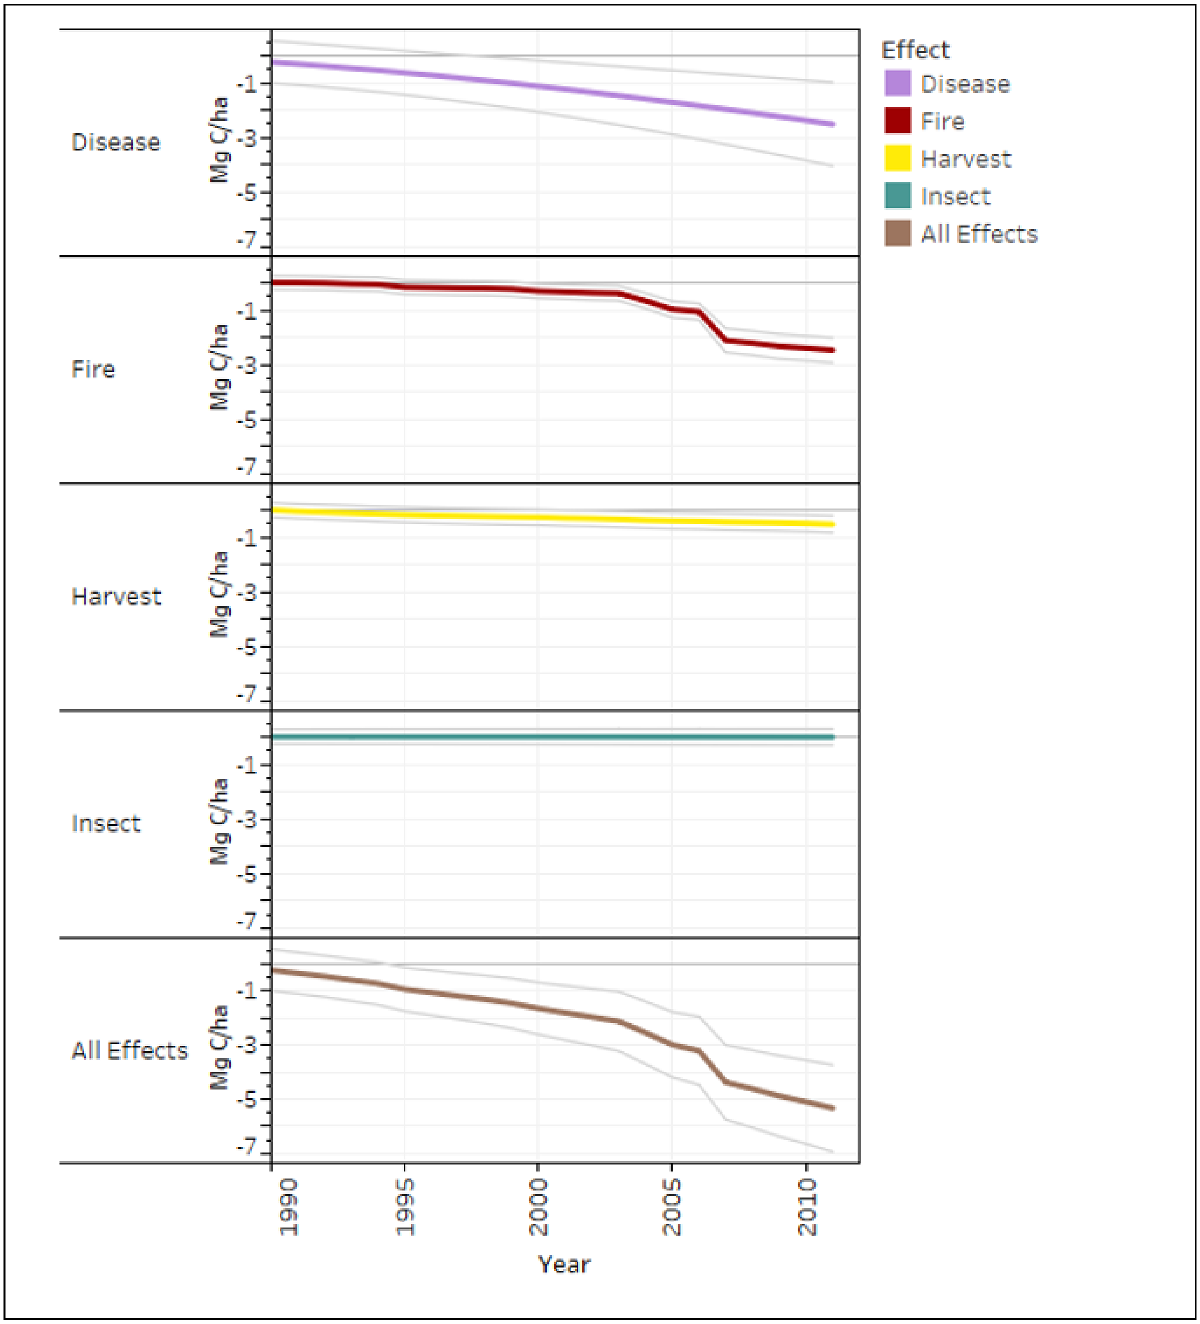

Figure 29. Estimated lost potential carbon storage (in megagrams per hectare) from disturbance (1990 to 2011) in the plan area. The zero line represents a hypothetical undisturbed scenario. Gray lines indicate 95 percent confidence interval.

Data Source: Nez Perce-Clearwater Carbon Dashboard Report (2019); estimated using the Forest Carbon Management Framework (ForCaMF) model. See the project record for more information.

Climate and Environment

Modeling was used to estimate the effects of climate (temperature and precipitation), atmospheric carbon dioxide concentrations, and nitrogen deposition on forest carbon stock change and accumulation. Overall, the climate since 1950 has negatively affected carbon stocks on the Nez Perce-Clearwater relative to other factors (Figure 30). Conversely, modeling estimates suggest increased atmospheric carbon dioxide (CO_2 fertilization) and nitrogen deposition have had a positive effect on carbon accumulation on the Nez Perce-Clearwater, potentially enhancing growth rates and helping to counteract ecosystem carbon losses from disturbance, aging, and climate.

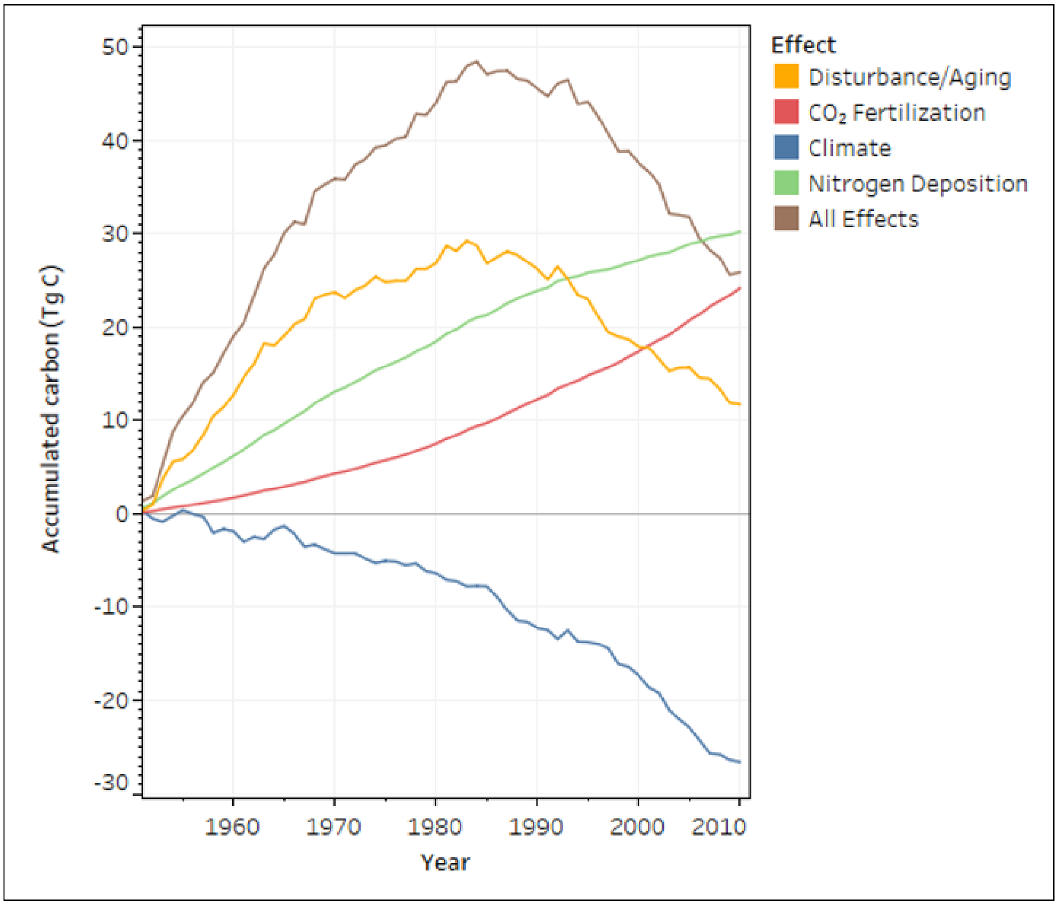

Figure 30. Accumulated carbon storage (in teragrams) in the plan area due to disturbance or aging, climate, nitrogen deposition, carbon dioxide fertilization, and all other factors combined (1950 to 2011), excluding carbon accumulated pre-1950.

Data Source: Nez Perce-Clearwater Carbon Dashboard Report (2019); estimated using the Integrated Terrestrial Ecosystem Carbon model. See the project record for more information. Environmental Consequences

Effects of the No Action Alternative

The effects of actions under the No Action Alternative would result in a similar pattern of carbon storage and flux, as described in the Affected Environment section above, because it represents a continuation of the status quo. Impacts to Forest carbon stocks could intensify though as future climate has the potential to influence all resources. The impacts of climate change on the capacity of ecosystems to store carbon are likely to vary across landscapes, and interactions with other landscape dynamics will add complexity. For example, rising temperatures can enhance forest growth and carbon storage, but this can be offset by reduced water availability during droughts. Changes in the frequency of fire due to temperature and precipitation changes will also modify carbon storage, especially where wildland fire reduces forest cover.

The 1987 Forest Plans do not contain any plan components directly related to carbon storage and sequestration, but they do provide direction on limiting soil disturbance and protecting wetlands, which can both store high amounts of carbon. Soil and forest floor carbon pools account for 42 percent of the overall Nez Perce-Clearwater carbon stock (Figure 27).

Effects Common to Action Alternatives

All action alternatives provide the same desired conditions for terrestrial ecosystems and the standards and guidelines that help achieve or maintain those conditions. Based on Land Management Plan guidance, management activities under all action alternatives would help maintain critical ecosystem functions into the future, in part by balancing the maintenance of carbon stocks and rates of carbon uptake. The following management strategies are incorporated into Land Management Plan direction under all alternatives that also influence carbon uptake and storage potential.

- Manipulate Nez Perce-Clearwater to provide for a variety of forest structures and compositions to support wildlife habitat. This can cause a decline in carbon stocks in some cases, such as when promoting early seral stands or more open stands but, compared with older stands, doing so promotes relatively high rates of carbon uptake over time as forests regrow (Pregitzer and Euskirchen 2004).
- Preserve, enhance, or accelerate the development of large tree stands and structures, and old-growth conditions to support higher carbon stocks in mature forests compared with younger stands (Harmon et al. 1990).
- Decrease forest densities and fuel conditions to reduce the risk of large, stand-replacing disturbance from insects, disease, and fire. Although this strategy initially reduces carbon stocks, it can lower risk for greater carbon stock losses and emissions in the future (Wiedinmyer and Hurteau 2010).
- Ensure successful reforestation after harvest or mortality-inducing disturbances to ensure continued carbon uptake and storage (Intergovernmental Panel on Climate Change 2014).
- Promote desired composition, structure, function, and ecological integrity pattern, which will support long-term carbon uptake and storage in the face of changing environmental conditions (Millar et al. 2007).
- Maintain or improve forest floor, ground cover, and coarse wood material to sustain continued carbon uptake and storage(Intergovernmental Panel on Climate Change 2014, Achat et al. 2015)
- Use harvested wood for valuable and renewable products to store carbon over the long-term and substitute for energy-intensive materials or fuels, reducing the net carbon emissions into the atmosphere (Gustavsson et al. 2006, Lippke et al. 2011).

Land Management Plan components guide where and how certain activities may occur on the landscape. All action alternatives include components addressing carbon storage and sequestration potential through maintenance or enhancement of biodiversity and function and managing for resilient forests. All action alternatives contain plan component FW-CARB-DC-01 that is specific to carbon storage and sequestration (Table 96). By including this plan component, the action alternatives would more explicitly provide for carbon storage and sequestration compared to the No Action Alternative. Table 96 provides the plan components that relate to carbon storage in the Land Management Plan and the expected effects of the direction.

Table 96. Summary of plan components related to forest carbon sequestration.

Plan component	Expected effects
FW-CARB-DC-01	The Land Management Plan recognizes the importance of the role of the Nez Perce-Clearwater related to carbon storage and sequestration, establishing a desired condition that directly addresses carbon sequestration. This desired condition focuses on sustaining this key ecosystem service through maintenance or enhancement of ecosystem biodiversity and function and managing for resilient forests adapted to natural disturbance processes and changing climates. This approach to management of forests for purposes of contributing to climate change mitigation is supported by a number of scientific sources (Hurteau et al. 2008, North and Hurteau 2011, Reinhardt and Holsinger 2010, Ruddell et al. 2006, Ryan et al. 2010, Schaedel et al. 2017, Wiedinmyer and Hurteau 2010).
TE, FOR, FIRE, GS, INV, RMZ	Desired conditions and objectives for vegetation, as found in Terrestrial Ecosystems; Forestlands; Fire Management; Meadows, Grasslands, and Shrublands; Invasive Species; and Riparian Management Zones sections, and the standards and guidelines that help achieve them, are designed to maintain and create resilient ecosystems. Management tools available to achieve these desired conditions would include wildland fire, timber harvest and fuels treatments, planting, thinning, and invasive species treatment. The aboveground live, belowground live, and understory carbon pools accounted for 47 percent of the carbon stock in the Nez Perce-Clearwater in 2013 (Figure 27).
FW-DC-SOIL-01, FW-STD-SOIL-01	Describes desired condition and directs management activities to be designed and implemented in a manner that maintains soil function and productivity. The soil carbon pool accounted for 23 percent of the carbon stock on the Nez Perce-Clearwater in 2013 (Figure 27).
MA2 and MA3-GDL-FOR-01	Sets coarse wood material requirements based on Graham et al. (1994) to ensure sufficient levels of organic materials. Down wood material stores carbon, accounting for 5 percent of the carbon stock on the Nez Perce-Clearwater in 2013 (Figure 27).
FW-DC-SOIL-02, FW-GDL-SOIL-02	Describes desired condition and sets an 85 percent target for effective ground cover, such as litter, fine and coarse woody material, or vegetation, which stores carbon. Forest floor, down wood, and understory carbon pools accounted for 25 percent of the carbon stock on the Nez Perce-Clearwater in 2013 (Figure 27).
MA2 and MA3-DC-FOR-10, MA3-STD-FOR-01, MA2 and MA3-GDL-FOR-02, MA2 and MA3-GDL-FOR-03, MA2 and MA3-GDL-FOR-04	Outline desired condition and requirements for old growth stands and limits fragmentation of old growth stands. These forests would fluctuate in location and abundance over time based on natural disturbances and successional processes. Plan components promote the creation of resilient old growth by emphasizing the establishment of the types of old growth that were historically most important, longest-lived, and most prevalent. By creating resilient old growth that is persistent over the long-term, there could be an increase the amount of carbon sequestered.
FW-DC-TE-02, FW-DC-WTR-08, FW-STD-RMZ-07	Describe desired conditions for groundwater dependent ecosystems, including peatlands, bogs, fens, and wetlands to maintain resiliency to changes in climate and other stressors and delineate riparian management zones. Decomposition of vegetation is slower in wetland areas, leading to the accumulation of organic matter. As a result, wetlands can accumulate large carbon stores, making them an important sink for atmospheric carbon dioxide (Nahlik and Fennessy 2016).

One of the emerging issues facing the U. S. Forest Service is how to manage for natural resource sustainability and meet public needs while also addressing other desired future conditions, such as increasing or maintaining forest carbon sequestration as a tool for climate change mitigation (McNulty et al. 2017). The Forest Service is subject to the Multiple-Use Sustained-Yield Act, requiring national forest lands to provide resources for outdoor recreation, range, timber, watershed health, and wildlife and fish habitat. Managing stands only for carbon storage and sequestration can reduce other key ecosystem services (Schwenk et al. 2012). McNulty et al. (2017) suggests using a multi-scale evaluation process, considering carbon management objectives in the broader context of trade-offs with other forest benefits that are managed at the local scale. Carbon stewardship seeks to optimize carbon within the context of ecosystem integrity and climate adaptation, not to maximize carbon at the expense of forest health or habitat.

Biogenic carbon refers to carbon cycling processes naturally occurring in ecosystems, such as the uptake of atmospheric carbon dioxide through photosynthesis and storage as biologically based materials, known as ecosystem carbon stocks. Biogenic greenhouse gas emissions are those that are related to the natural carbon cycle. Typical Forest Service projects that result in biogenic emissions include vegetation management activities such as timber harvesting, fuels reduction, habitat restoration, and invasive plant removal. Carbon is released when biologically based materials are combusted, harvested, decomposed, or otherwise processed as part of Forest Service management activities. The key point is that there is no ecological type-change, meaning forests or grasslands remain as such after a proposed action is implemented.

Management activities may initially remove carbon from the forest ecosystem, but they can also result in long-term maintenance or increases in forest carbon uptake and storage by improving forest health and resilience to various types of stressors (McKinley et al. 2011). Collectively, Land Management Plan direction would result in short-term losses of carbon in some cases, such as allowing for vegetation treatments, and storage of carbon on the landscape in some cases, such as retaining old growth and soil ground cover, but generally would result in maintaining the capacity of the landscape to sequester carbon by managing for native vegetation and natural disturbance processes.

Vegetation management or natural disturbances on national forest lands are not considered deforestation but rather an altering of stands to a more open state, or the conversion of forests back to the early successional stage of development and the initiation of new forests through regeneration. The forests on the Nez Perce-Clearwater have been cycling through this natural succession process for millennia. Forests are dynamic systems that naturally undergo ebbs and flows in carbon storage and emissions as trees establish and grow, die with age or disturbances, and re-establish and regrow.

The No Action and each of the action alternatives propose varying levels of acres to be treated using harvest, fuels treatments, or prescribed fire; however, the values are similar when considered at the forest scale and would have similar effects on carbon. The action alternatives all propose 53,000 to 64,500 acres of disturbance and restoration per year, including wildfire, prescribed fire, timber harvest and other fuels treatments designed to meet desired conditions and be consistent with natural range of variability.

The evaluation of the effects to carbon stocks from the action alternatives is a modeling exercise that provides information to compare alternatives. The resulting estimates do not reflect true outcomes. Additional site specific carbon analysis would occur for future projects implemented under the Land Management Plan. The harvest and fuels treatments objective for the Preferred Alternative is an average 10,000 acres per year, or about 0.3 percent of the total forested area (3,745,053 acres) on the Nez Perce-Clearwater. Based on satellite imagery, total estimated harvest disturbance from 1990 to 2011 was 30,349 acres, or an average of 1,446 acres per year (Hoang et al. 2019). The Preferred Alternative proposes an increase of about seven times the annual harvest area when compared to past harvest levels. If annual carbon impact also increases up to seven times above past levels, harvest treatments under this alternative may result in a maximum removal of about 260,100 Mg of carbon (0.26 Tg C) per year from aboveground pools.

The Preferred Alternative also includes an objective for prescribed burning of an average 6,800 acres annually and an objective for managing natural, unplanned ignitions of an average 36,000 acres annually. This is an increase of 4.5 times the annual fire compared to past levels from 1990 to 2011, which had an average 9,430 acres of fire disturbance per year (Hoang et al. 2019). If maximum levels of fire objectives occur, it would result in a potential loss of about 795,100 Mg of carbon (0.80 Tg C) annually, as estimated from the historical analysis.

Because wildfires are unpredictable, it is difficult to accurately estimate carbon loss on an annual basis. For example, as displayed in Figure 31 in the Fire Management section, from 2000 to 2019, fires burned on average approximately 74,750 acres annually. For the two previous decades, from 1980 to 1999, wildfires burned on average approximately 16,400 acres annually. From 1980 to 2019 annual wildfire acres ranged from less than 100 to approximately 232,800.

Considering the maximum area treated with timber harvest, thinning, fuels treatments, prescribed fire, and managing unplanned, naturally ignited fires in the Preferred Alternative, potential vegetation management actions would affect approximately 1.4 percent of the forested area annually. The amount of carbon that might be removed is an estimated 1.06 Tg C or approximately 0.4 percent of the approximately 279.43 Tg C stored in the forest ecosystem of the Nez Perce-Clearwater. The highest amount of projected carbon release would be under the No Action Alternative with an estimated loss of 1.2 Tg C. Alternative X resulted in the second highest amount, with an estimated 1.19 Tg C removed, followed by Alternative W with an estimated 1.13 Tg C released. Alternatives Y and Z had the lowest estimated amounts with Alternative Y resulting in a loss of 1.01 Tg C and Alternative Z showing a loss of 0.89 Tg C. Even if no management occurred on the Nez Perce-Clearwater, loss of carbon would still occur from other disturbance factors, such as wildfire and insect and disease. Although the action alternatives vary in the expected levels of vegetation management, these differences are negligible when compared at the Forest scale. Even more difficult is the ability to quantify potential carbon consequences of management alternatives in the future due to potential variability in future conditions and the stochastic nature of disturbances. The result of such uncertainty is often a very low signal-to-noise ratio. Small differences in carbon impacts among management alternatives, coupled with high uncertainty in carbon stock estimates, make the detection of statistically meaningful differences among alternatives highly unlikely.

The action alternatives would not significantly, adversely, or permanently affect forest carbon storage. Implementation of the Preferred Alternative could lead to a more resilient forest condition that could improve the ability of the Nez Perce-Clearwater to maintain carbon stocks and enhance carbon uptake.

Effects to Carbon Stocks from Other Resources

Terrestrial vegetation

All action alternatives provide the same desired conditions for terrestrial vegetation and the standards and guidelines that help achieve or maintain those conditions. Plan components associated with terrestrial vegetation provide direction for the management of forested and non-forested plant communities to trend towards the natural range of variation, therefore ensuring that the carbon sequestration capacity is maintained over the long term on the Nez Perce-Clearwater. Plan components for terrestrial vegetation can be found in the Terrestrial Ecosystems; Forestlands; Fire Management; Meadows, Grasslands, and Shrublands; Invasive Species; and Riparian Management Zones sections. The No Action Alternative does not prescribe desired conditions based on the natural range of variation but does provide direction for enhancing native vegetation communities and, therefore, would provide a similar potential for carbon sequestration.

Based on Land Management Plan guidance, management activities under all action alternatives would help improve composition, structure, and function of forests and grasslands; restore fire-adapted ecosystems; and provide for stable and improved forest and grassland health conditions. Implementing management actions to achieve this desired mix of conditions would enhance the overall ecological integrity of the forest ecosystems, improving their ability to adapt to potential stressors. These proposed activities will help maintain critical ecosystem functions into the future, in part by balancing the maintenance of carbon stocks and rates of carbon uptake.

Old growth forests are ecosystems distinguished by old trees and related structural attributes. Old growth forests provide particularly concentrated sites for carbon sequestration on the landscape. These forests would fluctuate in location and abundance over time based on natural disturbances and successional processes, regardless of alternative. Plan components specific to old growth under the action alternatives promote the creation of resilient old growth by emphasizing the establishment of the types of old growth that were historically most important, longest-lived, and most prevalent. By creating resilient old growth that is persistent over the long-term, the action alternatives would increase the amount of carbon sequestered. The No Action Alternative also includes minimum retention of certain proportions of old growth on the landscape but would not necessarily result in an increase in overall abundance of these areas relative to the existing condition.

Fire and fuels Management

Of all the potential disturbances on the landscape, wildland fire—both natural and planned ignitions—would have the greatest potential to cause short-term reductions in carbon stocks by removing vegetation, as well as causing carbon emissions. However, fire is also a primary mechanism for restoring and maintaining native vegetation with conditions consistent with the natural range of variation, thereby contributing to carbon sequestration potential over the long term. Prescribed burning and hazardous fuels reduction may indirectly reduce the risk of more severe wildfires and greater carbon losses in the future (Agee and Skinner 2005, Wiedinmyer and Hurteau 2010).

Plan components for fire and fuels management would help ensure the long-term sustainability of vegetation communities while also allowing for flexibility in allowing fire to play its natural role on the landscape. The action alternatives propose to continue to use wildland fire to create young stand conditions, reduce hazardous fuels, promote fire-adapted species, and encourage natural fire-return intervals. By promoting natural fire-adapted vegetation and forest resiliency, all the action alternatives would create more advantageous conditions to support long-term forest health in a changing climate (adaptation) and reduce carbon emissions and maintain carbon stocks (mitigation) (Intergovernmental Panel on Climate Change 2007).

In some instances, it is desirable to reduce carbon stocks to ensure the continued provisioning of other ecosystem services and for protecting lives and property. Hazardous fuel reduction treatments lower carbon stocks indefinitely if treatments are maintained. However, in the absence of fuels reduction treatments, the fire-adapted forest may be more at-risk to large and higher-severity wildfires, resulting in decreased ecosystem services and potentially increased carbon emissions. High-severity fires, especially when they occur repeatedly, can affect human health and safety, infrastructure, and ecosystem services and can cause delayed regeneration or even a transition of forests to non-forested ecosystems in some areas. By reducing the threat of uncharacteristic wildfire, management activities may create conditions more advantageous for supporting forest health in a changing climate and reducing greenhouse gas emissions over the long term. Furthermore, the reduction of stand densities is consistent with adaptation practices to increase resilience of forests to climate-related environmental changes (Halofsky, Peterson, et al. 2018a).

Timber Harvest

The U.S. Department of Agriculture's Building Blocks for Climate Smart Agriculture and Forestry (2016a) plan outlines two strategies to reduce greenhouse gas emissions—stewardship of federal forests, which emphasizes vegetation restoration and reforestation, and promotion of wood products.

Implementation of Land Management Plan direction for forestlands and timber would cause a short-term, localized reduction of carbon sequestration through the removal of living vegetation. Although the release of carbon is short-term, it could take several decades before reforested areas sequester carbon at the same rate. The amount of carbon expected to be influenced by harvest under any of the alternatives is less than one percent of the amount of carbon that the Nez Perce-Clearwater contains. Plan components that guide timber harvest and vegetation management, including desired vegetation conditions, would ensure that forest resiliency is promoted by these activities and, therefore, timber harvest would contribute to the long-term capacity of forests to sequester carbon.

Sustainable forestry practices can increase the ability of forests to sequester atmospheric carbon while enhancing other ecosystem services, such as improved soil and water quality. Planting new trees and improving forest health through thinning and prescribed burning are some of the ways to increase forest carbon in the long run. Harvesting and regenerating forests can also result in net carbon sequestration in wood products and new forest growth. In the absence of thinning and harvesting, the forest will thin from natural disturbances and other processes associated with natural succession, such as age-related mortality or competition. The resulting dead trees will continue to store carbon, and they will also decay over time, emitting carbon into the atmosphere.

Under all alternatives, management activities involving timber harvest can result in both long-term carbon storage off site and substitution effects through the use of harvested wood products. Carbon can be stored in wood products for days to centuries, depending on the commodity produced and end use. As more commodities are produced and remain in use, the amount of carbon stored in products increases, creating a cumulative benefit when considered with forest regrowth. Even as more wood products are discarded, the carbon stored in solid waste disposal sites also increases. Harvested wood products can also substitute for more fossil fuel-intensive materials like steel, concrete, and plastic, resulting in a net decline in emissions (Dugan et al. 2018, McKinley et al. 2011, Gustavsson et al. 2006, Lippke et al. 2011). Likewise, harvested wood and discarded wood products can be burned to produce heat or electrical energy, also producing a benefit by substituting for more carbon-producing energy sources. The Intergovernmental Panel on Climate Change recognizes wood and fiber as a renewable resource that can provide lasting climate-related mitigation benefits that can increase over time with active, sustainable management (Intergovernmental Panel on Climate Change 2000). Although not quantified in this document, it is acknowledged that there would be an increase in fossil fuel carbon emissions from the use of equipment during the harvest activity and the transport of timber from the stand to processing facilities. While these emissions represent a reduction in the amount of estimated carbon sequestered in harvested wood products, the magnitude of haul emissions is difficult to calculate at the programmatic level, particularly due to the variation in distance timber must travel to reach milling facilities.

As outlined in: Effects of Climate Change on Forest Vegetation in the Northern Rockies (Halofsky, Peterson, et al. 2018a), timber harvest, prescribed fire, and managing wildland fire can be adaptation options that address climate change effects on forested vegetation. These vegetation management actions can be used to treat departed vegetation conditions, creating more resilient and diverse forests. Reducing stand density may also reduce the risk of more severe disturbances, such as insect and disease outbreak and severe wildfires, which could result in lower forest carbon stocks and greater greenhouse gas emissions. In the absence of timber harvest, forests thin naturally from mortality-inducing natural disturbances and other processes resulting in dead trees that would decay over time, emitting carbon to the atmosphere.

All the action alternatives include plan components (MA2 and MA3-GDL-FOR-01, FW-GDL-SOIL-02) that set requirements for maintenance of down wood and ground cover during timber harvest and fuels treatment activities. These carbon pools accounted for approximately 25 percent of the carbon stock in the Nez Perce-Clearwater in 2013 (Figure 27).

Mining and mineral extraction

Mining and mineral extraction actions undergo site-specific National Environmental Policy Act analysis to determine effects and required mitigation. Effects to vegetation, ground cover, and soil from mining are determined at the project level. The impacts to carbon stores from mineral extraction on Nez Perce-Clearwater would be localized and insignificant at the forestwide scale. Land management plan standards and guidelines and best management practices would lessen effects of vegetation and ground cover removal and soil disturbance.

Livestock grazing

In all alternatives, livestock grazing would occur on the Nez Perce-Clearwater. Permitted numbers of livestock and season of use would be the same for all alternatives. Plan components would ensure that livestock grazing is managed in a manner that would maintain desirable vegetation communities and, therefore, would not preclude the carbon sequestration potential of rangelands under any alternative.

The Environmental Protection Agency (2019) estimates that about 47 percent of the total greenhouse gas emissions in the agricultural sector are attributed to livestock. In turn, the agricultural sector contributes to about 9 percent of total greenhouse gas emissions in the United States. The USDA's National Agricultural Statistics Service estimated in January 2019 that the United States had about 94.8 million cattle (National Agricultural Statistics Service 2019). By comparison, Nez Perce-Clearwater permits approximately 4,600 cattle (29,861 animal unit months). Livestock are present on the national forest at most 6 months out of the year. Permitted season of use varies by allotment, ranging from six weeks to six months. Seasons on some allotments start as early as May 1 and some end as late as October 31. Active livestock grazing allotments occur on about 15 percent of the Nez Perce-Clearwater. Using 4,600 permitted head of cattle and a maximum six month season of use for each animal, it is estimated that livestock produce approximately 167 tons or 0.0002 teragrams of methane emissions per year. See the Carbon on Non-Forest Lands Section in Appendix D for more information.

Invasive Plants

Increases in atmospheric carbon levels and higher temperatures would likely make invasive species, especially annual grasses, more competitive and adaptable, which may allow some species to expand to higher elevations as well as become more difficult to control due to reduced chemical efficacy (Ziska et al. 2004). Not only will some species become more invasive, but the array of species would continue to change (Scott et al. 2013). Invasive species infestations can impact native plant communities and alter disturbance regimes, potentially leading to declines in carbon storage. The Land Management Plan includes desired conditions and objectives to prevent new invaders and limit the spread of existing invasive species.

Aquatic habitat, riparian management zones, and water resources

Measures to protect aquatic habitat, riparian management zones, and watersheds would generally result in vegetation being maintained as needed for watershed function and would result in a greater likelihood of vegetation cover being maintained within riparian management zones specifically. These measures would be greater for the action alternatives than the No Action Alternative. The retention of vegetation in riparian areas would provide areas of refugia, potential old growth, and seed sources to contribute to the overall resilience and, therefore, carbon sequestration potential of vegetation on the landscape over time.

Wetland soils contain some of the highest stores of soil carbon in the biosphere and are an important sink for atmospheric carbon dioxide (Nahlik and Fennessy 2016). Decomposition of vegetation is slower in wetland areas, leading to the accumulation of organic matter. As a result, wetlands can accumulate large carbon stores. The Land Management Plan includes desired conditions for wetlands to persist in size and seasonal and annual timing and exhibit water table elevations within the natural range of variability (FW-DC-WTR-08) and maintain resiliency to changes in climate and other stressors (FW-DC-TE-02). Wetlands are included in the riparian management zone delineations (FW-STD-RMZ-07) and standards and guidelines associated with water resources and riparian management zones would be followed to conserve wetland areas.

Cumulative Effects

Climate change is a global phenomenon because major greenhouse gases mix well throughout the planet's lower atmosphere. Estimated emissions of greenhouse gases in 2010 were 13,336 plus or minus 1,227 Tg carbon globally (Intergovernmental Panel on Climate Change 2014) and 1,881 Tg carbon nationally (U.S. Environmental Protection Agency 2015). All of the plan alternatives are projected to contribute negligibly to overall greenhouse gas emissions. The estimated loss of approximately 1.1 Tg C annually based on the Preferred Alternative is small relative to the approximately 279.43 Tg C of carbon stored in the forest ecosystem in the Nez Perce-Clearwater.

Portions of the Nez Perce-Clearwater adjoin other national forests, each having its own land management plan. The Nez Perce-Clearwater also borders and is intermixed with lands of other ownerships, including private lands, other federal lands, and state lands. Land management plans for state and federal agencies would broadly provide for resilient forest conditions and not reduce the potential of lands to store and sequester carbon; as such, they would be complementary to the proposed land management plan. Adjacent private lands would not necessarily be managed for retention of native vegetation; for example, potential housing developments or shift to agriculture could reduce carbon storage potential on some of these lands.

Currently, the U.S. Forest Service does not participate in carbon markets. Congress has not given the U.S. Forest Service the authority to allow National Forest System lands to participate in carbon markets or produce carbon credits. However, organizations can partner with the U.S. Forest Service in needed restoration work to improve carbon sequestration, forest health, and resilience to climate change.

Conclusion – Climate Change and Carbon Stocks

The proposed activities under all action alternatives generally maintain and improve forest health and resiliency to disturbances. Potential negative effects may be mitigated and completely reversed with time as the forests regrow. Over the longer term, the activities proposed in the plan are likely to increase carbon storage and reduce emissions by reducing disturbance risk and storing carbon in wood products. The management mechanisms applied in all plan alternatives are consistent with internationally recognized climate change adaptation and mitigation practices identified by the Intergovernmental Panel on Climate Change (D'Amato et al. 2011, Intergovernmental Panel on Climate Change 2007, 2000).

Carbon stocks on the Nez Perce-Clearwater will likely continue to increase or remain stable under all plan alternatives into the foreseeable future. Natural ecosystem processes, including forest growth (succession) and small-scale disturbances, such as wildland fire, insects, and harvest, would continue to influence carbon stocks and emissions, but they are not expected to significantly change current trends in carbon over the span of the plan. All alternatives would preserve existing National Forest System lands and forests by improving forest conditions and retaining forest characteristics by maintaining current land use. Given the likely changes in land use in coming decades on adjacent land ownerships, this is a critical goal.

3.2.4 Fire Management

Fire is a necessary and critical ecological function across the Nez Perce-Clearwater that plays a central role in providing quality habitat for both plant and wildlife species. Wildland fire refers to both wildfire (unplanned ignitions) and prescribed fire (planned ignitions). Wildland fire management includes all activities for the management of wildland fires to meet land management objectives. Fire management includes the entire scope of activities from planning, prevention, fuels or vegetation modification, prescribed fire, hazard mitigation, fire response, rehabilitation, monitoring, and evaluation. The management of wildland fire influences whether fire effects have beneficial or non-beneficial impacts on resources such as air and water quality, wildlife habitat, recreation areas, and communities. Wildland fire management incorporates a spectrum of responses ranging from full suppression to managing for land management plan objectives. Suppression is a management strategy used to extinguish or confine all or a portion of a wildfire. Fuels management is the practice of controlling flammability and reducing resistance to controlling wildland fuels through mechanical, chemical, biological, or manual means, or by fire in support of land management objectives. Fuels treatments result in a change in the amount, configuration, and spacing of live and dead vegetation, creating conditions that result in more manageable fire behavior and reduced intensity during future wildland fire events.

Wildland Fire Management

Fire on the landscape is considered a natural process and most fires on the Nez Perce-Clearwater are started by lightning. However, humans have also been a source of fire on the landscape for centuries and, whether intentional or not, have influenced vegetation dynamics. Fire is not a simple process. Many factors influence its character, including fuel characteristics, climate, weather conditions, topography, vegetation characteristics, and elevation.

All wildland fires are managed on a continuum between meeting protection objectives and achieving resource objectives. These objectives come from desired conditions within the Land Management Plan. Environmental conditions that influence how a given fire burns change throughout the season and from year to year, providing both opportunities and restrictions. Where a specific fire falls on this continuum is based both on the location of the wildfire and the conditions in which it is burning.

Forest Service policy dictates that every management response to wildfire must include some aspect of a protection objective (National Interagency Fire Center 2019). This response can vary from monitoring the fire under conditions that are conducive to obtaining resource benefits to an aggressive suppression effort to protect communities and natural resources from potential damages. Factors in all wildfire management decisions include firefighter safety; public safety; risk to property; fire resource availability; national, regional, and forest priorities; costs; and potential resource benefits. All human-caused wildfires require a suppression strategy.

The management of wildland fires that reduce fuels and improve ecosystem conditions is characterized as managing fires, or portions of them, to meet Land Management Plan resource objectives. These fires tend to have effects that are similar to or trend towards desired future conditions. Managing wildfires to meet land management plan objectives is a strategic choice to use natural ignitions to restore or maintain the ecological function of fire in fire dependent landscapes. Some of the benefits of managing wildland fires to meet land management plan objectives are reducing fuel loadings so that future fires in that area burn with lower intensity (Parks, Holsinger, et al. 2015), lesser impacts, and reduced smoke production. Benefits may also include creating a mosaic and diversity of wildlife habitats, accelerated nutrient cycling into the soil (Hungerford et al. 1991), and reducing forest density to favor fire-resistant species (Agee 1993). This results in a more fire resilient ecosystem.

Circumstances leading to wildfire suppression include fuel and weather conditions, proximity to values at risk, time of year, and expected detrimental fire effects that would not improve or maintain landscape desired conditions. However, when natural fires are suppressed in fire adapted ecosystems, there could be detrimental effects to vegetation composition and structure, ecosystem process, soil dynamics, wildlife habitat, and biodiversity (Keane et al. 2002). In combination with climate change, land use change, and twentieth century fire exclusion, suppression of wildfires also increases the existing fire deficit (Marlon et al. 2012).

Effective management of wildland fire addresses the nature of wildfire and its contributing factors, recognizes the positive and negative consequences of fire, addresses uncertainty, and develops responses that reduce the chances of catastrophic losses (U.S. Department of Agriculture and U.S. Department of the Interior 2014b). Forest and fire managers consider the short and long-term risk of managing each wildland fire event. If consequences of each wildland fire are recognized and management actions to obtain positive outcomes are matched, then the long-term risk to resources and assets will be reduced, fire as an ecosystem function on the landscape will be restored, and smoke impacts to communities will be reduced.

Fuels Management

Fuels reduction treatments consist of thinning and prescribed fire but also include other mechanical, biological, chemical, and manual treatments. Prescribed fires are purposely ignited by managers in accordance with applicable laws, policies, and regulations to meet specific objectives. Mechanical treatments include the use of equipment to perform activities that change vegetation composition and structure which alter fuels and reduce hazards. Mechanical treatments are often followed up with prescribed burning for the most effective fuels reduction treatments (Prichard et al. 2010). The focus of the fuels management program has been to modify the fuel conditions to meet varying objectives to reduce threats to values at risk, increase suppression success by minimizing crown fire potential, decrease fire intensity, or decrease rate of spread.

Fuels reduction treatments focus on the part of the fire environment that can be altered, resulting in a change in the amount, configuration, and spacing of live and dead vegetation. The costs, environmental impacts, and effectiveness of different fuel treatment types vary. Desired outcomes of fuels treatments include decreased fire intensities and severity during consequent wildfires (Reinhardt et al. 2008). Additional benefits could include the minimization of impacts to high value resources and assets and reducing fire spread to other ownerships. Strategically located fuels treatments could also provide opportunities to proactively manage the size and costs of future wildfires (Thompson et al. 2013). Fuel reduction treatments can slow rate of spread, shift fire behavior from crown fire to surface fire, and decrease fire severity within previously treated areas. Treatment areas are only effective for a finite length of time and may need periodic maintenance to remain effective. In addition, fuel treatments can achieve multiple resource benefits, such as meeting desired vegetation conditions, creating desired wildlife habitat, and producing timber products.

The vegetation matrix of the wildland urban interface will carry fire when the conditions permit; these interface lands are becoming more densely populated each year. The wildland urban interface designation affects all fire management decisions in those interface areas. Although a wide variety of fire management strategies are available to implement, these options are usually narrowed due to concerns that fire may move from federal to private lands, or vice versa. Hazardous fuels treatments in the wildland urban interface are focused on manipulating the vegetation to enhance the success of fire suppression activities.

Relevant Laws, Regulations, and Policy

Federal Laws

Clean Air Act (USC 7401) of 1970, as amended: This act provides for the protection and improvement of the nation's air resources and applies to the effects of prescribed fire and can help inform wildfire response.

Healthy Forest Restoration Act of 2003 (HR 1904): Aimed at expediting the preparation and implementation of hazardous fuels reduction projects on federal land; encouraging collaboration between federal agencies and local communities; requires courts to balance effects of action versus no action prior to halting implementation; and requires federal agencies to retain large trees under certain conditions.

2002 President’s Healthy Forest Initiative: Emphasizes administrative and legislative reforms to expedite fuels treatments and post-fire rehabilitation actions.

Infrastructure Investment and Jobs Act of 2021 (H.R. 3684; Title VIII National Resources Related Infrastructure, Wildfire Management and Ecosystem Restoration) Section 40803: Wildfire Risk Reduction; Directs the United States Forest Service to conduct restoration treatments and improve the Fire Regime Condition Class of 10,000,000 acres that are located in the wildland-urban interface or a public drinking water source area by September 30, 2027. Section 40807; Emergency Actions: The law authorizes the United States Forest Service to take emergency actions to protect public health and safety, critical infrastructure, and natural resources on National Forest System lands.

Policy

Forest Service Manual (FSM 5100): Provides direction on wildland fire including suppression and fuels management, including prescribed fire in general and within wilderness.

Forest Service Handbook 5109: Provides direction for wildland fire managers.

National Fire Plan, August 2000: Outlines a plan of action for federal agencies in order to protect wildland urban interface and be prepared for extreme fire conditions.

Federal Wildland Fire Management Policy of 1995 (updated January 2001): Guides the philosophy, direction, and implementation of wildland fire management on federal lands.

Interagency Rx Fire Planning and Implementation Procedures Guide 2022 (PMS 484): Provides standardized procedures, specifically associated with the planning and implementation of prescribed fire.

Guidance for Implementation of Federal Wildland Fire Management Policy 2009: Guidance for consistent implementation of the 1995/2001 Federal Fire Policy.

National Cohesive Wildland Fire Management Strategy 2014: The National Cohesive Wildland Fire Management Strategy is a strategic push to work collaboratively among all stakeholders and across all landscapes, using best science, to make meaningful progress towards the three goals:

1. Resilient Landscapes
2. Fire Adapted Communities
3. Safe and Effective Wildfire Response

Interagency Standards for Fire and Fire Aviation Operations (NFES 2724): A reference guide that documents the standards for operational procedures and practices for the Forest Service fire and aviation management program.

State and Local Plans

The following plans provide guidance for sustained action taken to reduce or eliminate the long-term risk to human life and property from hazards. Mitigation activities pertaining to wildfires, hazard fuels, and zonal planning may be implemented prior to, during, or after an incident (State and Local Land Management Plans)

- Lewis County, Idaho Multi Hazard Mitigation Plan (2011)
- Clearwater County, Idaho Multi Hazard Mitigation Plan (2017)
- Idaho County, Idaho County Multi-Hazard Mitigation Plan (2022)
- Latah County, Multi Hazard Mitigation Plan (2011)
- Nez Perce County, Comprehensive Plan (2018)

Measurement Indicators

The following measurement indicators were used for assessing fire management.

Restoration and Maintenance of the Ecological Role of Fire: Measured by projected acres of wildfire within fire regime groups.

Future Fuels Treatments: Measured by acres of projected mechanical treatments and prescribed fire.

Fire Management Flexibility: Measured by acres of land allocations that influence the flexibility to carry out mechanical and prescribed fire treatments and manage unplanned ignitions.

Methodology and Analysis Process

The vegetation management strategy for the Nez Perce-Clearwater is to manage the landscape to maintain or trend towards vegetative desired conditions. Fire is a primary natural disturbance process that changes vegetation conditions within the Nez Perce-Clearwater's ecosystems. Fuels management consists of management activities designed to alter vegetation conditions to achieve desired results. One desired result is the potential reduction in fire intensity and consequent risk to resources and communities. Therefore, the analysis process for determining past, present, and future vegetation conditions provides the basis for the analysis of fire and fuels treatments in this section of the environmental impact statement.

Modeling was used to estimate the extent and effects of disturbance processes by looking at historical fire events to develop a natural range of variation to project future wildfire. Planned and unplanned fire; insects, such as bark beetles; diseases, such as root disease; and harvest treatments are the main drivers of vegetative change interacting with climate and the process of vegetative succession. The main analytical models used were the SIMulating Patterns and Processes at Landscape scaLEs model, commonly referred to as SIMPPLLE (Chew, Bollenbacher, et al. 2012), and the PRISM model, which provides plan-level forest activity scheduling projections (Nguyen 2018).

The SIMPPLLE and PRISM models are used in the Northern Region for plan revision. For further details, refer to the Forestlands section and Appendix B. The analysis assumes climate trends will continue to be warmer and drier than historical conditions (Intergovernmental Panel on Climate Change 2014), naturally ignited wildfire will continue to be the largest contributor to fuels management and development in the wildland-urban interface will continue. Additionally, under warmer and drier conditions, it is anticipated that large fire activity will continue to increase in the future and that fire seasons will be longer than historically observed (Brown et al. 2004).

Naturally ignited wildfire will continue to be the largest contributor to fuels management. The use of wildland fire as a tool to meet land management plan objectives may occur on all acres in all Action Alternatives so long as those fires are moving the landscape towards or helping maintain the desired condition. Prescribed fire and other vegetation treatments will continue to contribute to fuels management as budgets and conditions allow.

With continued development into wildfire hazard areas, wildland urban interface boundaries identified in Community Wildfire Protection Plans will also change over the life of the plan. As the wildland urban interface expands, there will be an increased need to focus fuels treatments in these areas. The increase in human caused ignitions is also associated with the increased wildland urban interface (Syphard et al. 2007).

Information Sources

This analysis also draws upon the best available literature references that were found to be relevant to the ecosystems on the Nez Perce-Clearwater. Literature sources that were the most recent, peer-reviewed, and local in scope or directly applicable to the local ecosystem were selected. Uncertainty and conflicting literature were acknowledged and interpreted when applicable. In addition, local studies and anecdotal information that is not peer-reviewed are included where appropriate to provide context.

Climate data was compiled from the United States Climate Divisional Database from 1895 to 2017 for annual temperature and precipitation. The LANDFIRE database was accessed to collect the fire regime group and mean fire return interval data for each of the five fire regime groups. Best available information was used to build the fire logic and assumptions within the SIMPPLLE and PRISM models, including corroboration with actual data and professional knowledge and experience.

The historic fire occurrence and fire size data used for calibrating fire probabilities in the SIMPPLLE and PRISM models were derived from multiple sources. Forest fire occurrence data was gathered from the FIRESTAT database for fire ignition point data. Next, large fire polygons and prior fuels reduction treatments were obtained from the Forest Activity Tracking System (FACTS) database. Fire severity data was taken from Monitoring Trends in Burn Severity (MTBS) data, which uses only fires greater than 1,000 acres. This analysis did not include unburned acres or areas of increased greenness within fire perimeters.

Wildland-urban interface areas, as identified in Benewah, Clearwater, Latah, Lewis, and Idaho Counties' Community Wildfire Protection Plans, were used for analysis to inform the models where vegetation treatments could take place in relation to constraints of the Northern Rockies Lynx Management Direction (U.S. Department of Agriculture 2007f). Community Wildfire Protection Plans are "living" documents and are subject to change; therefore, the extent of wildland-urban interface will also change over the life of the plan. As of October 10, 2023, the extent of the wildland-urban interface on the Nez Perce-Clearwater is 1,458,924 acres. However, limitations due to budget, land allocation, and resource protections restrict where fuels treatments can be conducted. For additional information, see the Environmental Consequences section below.

Incomplete and Unavailable Information

Terrestrial ecosystems are highly complex and contain an enormous number of known and unknown living and non-living factors that interact with each other, often in unpredictable ways. For this reason, the Nez Perce-Clearwater acknowledges that there are gaps in available information and knowledge about ecological functioning and an inability to even evaluate what those gaps may be. These gaps in information may lessen over time as new information or methodology is devised. The Nez Perce-Clearwater's ability to predict fire or other disturbances into the future is limited and is subject to uncertainty. The level of uncertainty is determined by the level of uncertainty of such factors as natural disturbances, climate change, or human-caused influences.

Spatial Scale

The fire management analysis area encompasses those lands administered by the Nez Perce-Clearwater, as well as the land of other ownership within and adjacent to the Nez Perce-Clearwater. The SIMPPLE model included a 3-mile buffer outside the administrative boundaries of the Nez Perce-Clearwater to account for fire events that have migrated onto the forest from other landownerships.

Temporal Scale

The temporal scale of this analysis is 20 years. While the Land Management Plan is expected to be in place for 15 years, quantitative effects were derived from the SIMPPLLE and PRISM models, which use whole decades as the modeling time steps. Further, using the second time step rather than the first-time step more clearly demonstrates differences between alternatives.

Past, Present, and Future Activities used in the Analysis

Fire and fuels management activities, including timber harvest, non-commercial thinning, prescribed fire, and unplanned wildfire activities were used to develop this analysis. Past fires were analyzed against fire regimes to determine fires' natural range of variation and to determine whether fire has been playing its ecological role on the Nez Perce-Clearwater. Modeled fire occurrence and fuels treatments provide a reasonable representation of future conditions. Refer to the Forestlands section and Appendix B for information on modeling and other aspects of the analysis that also apply to fire management.

Significant acreages within the administrative boundary of the Nez Perce-Clearwater have been designated as roadless as a result of the Idaho Roadless Rule. These lands are subject to management limitations, which will have an impact on the extent to which forest wide management objectives can be met.

Notable Changes between the Draft and Final

In addition to providing new information and sources, clarifying language, minor edits, and analysis of the Preferred Alternative, the notable changes in the plan between draft and final include analysis of fire regimes using mean fire return interval to determine expected amount of fire to be within a fire regimes natural range of variability. The associated analysis in the final environmental impact statement highlights where fire deficits are most pronounced and how the current conditions of fire severity compare to what would historically have been expected, based on the fire regime.

Affected Environment

Existing Condition

Restoration and Maintenance of Fire Regimes

A fire regime represents the periodicity and pattern of naturally occurring fires, described in terms of frequency, biological severity, and aerial extent (U.S. Department of Agriculture 2010c). The natural fire regime is a classification of the role fire would play across a landscape in the absence of modern human intervention but including the influence of aboriginal fire use. Five natural fire regimes are classified based on the average number of years between fires, referred to as fire frequency or mean fire interval, combined with severity, defined as the amount of vegetation replacement, and its effects to the dominant vegetation (U.S. Department of Agriculture 2010c) (Table 97).

Table 97. Fire regime, acres, and percentage of distribution on the Nez Perce-Clearwater.

Fire Regime[1]	Definition[1]	Acres of National Forest System Land[2]	% Landscape
I	0 to 35-year frequency; non-lethal (low/mixed severity)	366,649	9.3%
II	0 to 35-year frequency; replacement (high severity)	17,233	0.44%
III	35 to 200-year frequency (mixed/low severity)	2,121,896	53.8%
IV	35 to 200-year frequency; replacement (high severity)	1,291,463	32.8%
V	Greater than 200-year frequency (any severity)	31,994	0.8%
Sparsely Vegetated	Non-burnable	2,154	<1%
Barren	Non-burnable	643	<1%
Snow/Ice	Non-burnable	570	<1%
Water	Non-burnable	6,993	<1%

[1]Table information is adapted from (Barrett et al. 2010).
[2]Acre summaries in this section may differ slightly due to the data source (raster data versus vector GIS data).
Data Source: Landfire 2010, v.1.2.0.

Prior to European settlement, cultural burning practices along with natural ignitions from lightning were the primary ignition source for fires (Barrett and Arno 1982). There have been several fire history studies completed throughout the Nez Perce-Clearwater to determine the historical fire frequencies and fire severities prior to the 1930s for the following areas. Within the upper Clearwater River drainages, there were extensive stand replacement forest fires in the cool and cool moist vegetation types that burned approximately every 200 plus years. In the upper North Fork, large stand replacement fires had mean fire return intervals greater than 250 years and patchy underburning mean fire return intervals were less than 100 years within the grand fir and Western redcedar warm moist vegetation types during the 1800s. In the lower South Fork Clearwater River, warm dry south facing stands of Douglas fir and Ponderosa pine were maintained by frequent low intensity fires in open stands, which suggests that the mean fire return interval was generally less than ten years. On the more productive slopes, there were multiple classes of Douglas fir, Ponderosa pine, and Western larch burned approximately every 20 to 60 years under mixed severity fires (Barrett 1993). In the river breaks zone within the River of No Return Wilderness, fire history studies concluded an approximate 5 to 50 year mean fire return interval with primary low severity fires within the Douglas fir and Ponderosa pine warm dry vegetation types (Barrett 1984).

Wildfires can be broadly divided into two principal regimes – natural and human-driven. Natural fires are caused by lightning and have historically made up a large percentage of the total fires. They historically burned under conditions that maintained or enhanced the characteristics of vegetation within each of the fire regimes.

Historical human ignitions also contributed to the maintenance of vegetation and the fire regimes. Currently, human-caused ignitions are unpredictable and can occur at any time in the year at any location. The most difficult fires for fire managers to address are on the hottest days and within the wildland urban interface where most human activity occurs.

The desired and existing average acres burned per decade from 1984 to 2021 by fire regime and severity are shown in Table 98This is the same data used in FW-OBJ-FIRE-01 but more in-depth to capture where fire deficits are most pronounced based on methods in (Ager et al. 2014).

Historically, large fires have occurred across the Nez Perce-Clearwater, as shown by fire history studies (Barrett 1993), GIS fire history database records, recent data (1940 to present), and anecdotal evidence (pre-1940). The only fire regimes at or above average in terms of expected burn acreage are Fire Regimes IV and V on the Nez Perce-Clearwater. These regimes represent 32.8 percent and 0.8 percent of the forest, respectively. This recent activity in the long fire return interval replacement severity Fire Regimes IV and V was mainly driven by large fires in 2012, 2015, 2017, and 2021. This recent activity can be attributed to drought and extremely dry fuels at higher elevations, busy fire seasons where responders were more focused on suppressing fires that threatened critical values at risk near towns and communities, and natural ignition fires playing their natural role in Wilderness areas. Fire has been reduced from playing its natural role especially within Fire Regimes I, II, and III. These fire regimes comprise 9.3, 0.44, and 53.8 percent, respectively, of the national forest. The absence of fire in these regimes is likely derived from the combination of cooler climatic conditions in the 1900s (Littell et al. 2009); reduced fuels from large fires in the early 1900s; the increasing capability of fire suppression technology, such as air tankers and aerially delivered firefighters; and the agency's focus on suppression.

The long-term deficit of abundant low- to moderate-severity fire has contributed to modification of seasonally dry forested landscapes across western North America and is also evident on the Nez Perce-Clearwater National Forests (Table 99). The magnitude of change in fire regimes and the resultant increases in forest density and fuel connectivity have increased the vulnerability of many contemporary forests to seasonal and episodic increases in drought and fire, exacerbated by rapid climate warming (Hagmann et al. 2021).

Table 98. Desired and Existing conditions for average amount and severity of wildland fire per decade by fire regime group.

Fire Regime Group[1]	Average Desired Acres Burned per Decade[2]	Existing Average Acres Burned per Decade[3]	Desired Fire Return Interval (Frequency)[1]	Desired Fire Severity[1,4]	Existing Low Severity Acres per Decade[5]	Existing Moderate Severity Acres per Decade[5]	Existing High Severity Acres per Decade[5]
I	173,000 to 218,000	45,919	0–35 years	Low to mixed	30,047	11,183	4,690
II	9,000 to 11,000	3141	0–35 years	High	2,838	277	26
III	286,000 to 325,000	89,579	35–200 years	Mixed to low	48,201	25,779	15,599
IV	70,000 to 91,000	111,496	35–200 years	High	36,026	38,250	37,220

Fire Regime Group[1]	Average Desired Acres Burned per Decade[2]	Existing Average Acres Burned per Decade[3]	Desired Fire Return Interval (Frequency)[1]	Desired Fire Severity[1,4]	Existing Low Severity Acres per Decade[5]	Existing Moderate Severity Acres per Decade[5]	Existing High Severity Acres per Decade[5]
V	600 to 1,100	2,423	200+ years	High to mixed to low	1,518	664	241
Total	538,600 to 646,100	252,557	not applicable	not applicable	118,629	76,151	57,776

Desired condition applies to all potential vegetation types.

[1]Fire regime groups, fire return intervals, and fire severity types, as defined in the Fire Regime Condition Class Guidebook (U.S. Department of Agriculture 2010c).

[2]Expected acres are the average range derived from Mean Fire Return Interval data from LANDFIRE 2012, v.1.3.0. Rounded to nearest hundred where applicable.

[3]Existing comes from 1984 to 2021 Monitoring Trends in Burn Severity data, wildfires greater than 1,000 acres. Does not include unburned areas within wildfire perimeters.

[4]First adjective indicates dominant severity. Mixed severity is defined as a combination of low to high fire severity within the perimeter of a single fire or across consecutive events.

[5]Fire severity classification is defined by Monitoring Trends in Burn Severity. Existing fire severity comes from 1984 to 2021 Monitoring Trends in Burn Severity data.

Wildfire History and Recent Trends

Historical fire data in the Nez Perce-Clearwater's geographic information system database shows wildfire areas burned from 1885–2022 (Figure 31). In this dataset, the earliest records may not be complete and often include only large fires or active fire years, creating the potential to underestimate the quantity and extent of older fires. The data is based on fire start records on National Forest System lands and does not include ignitions that went out prior to being detected. This fire history data has many influences, including fuels, weather (daily, monthly, and long term), ignition sources, and suppression efforts.

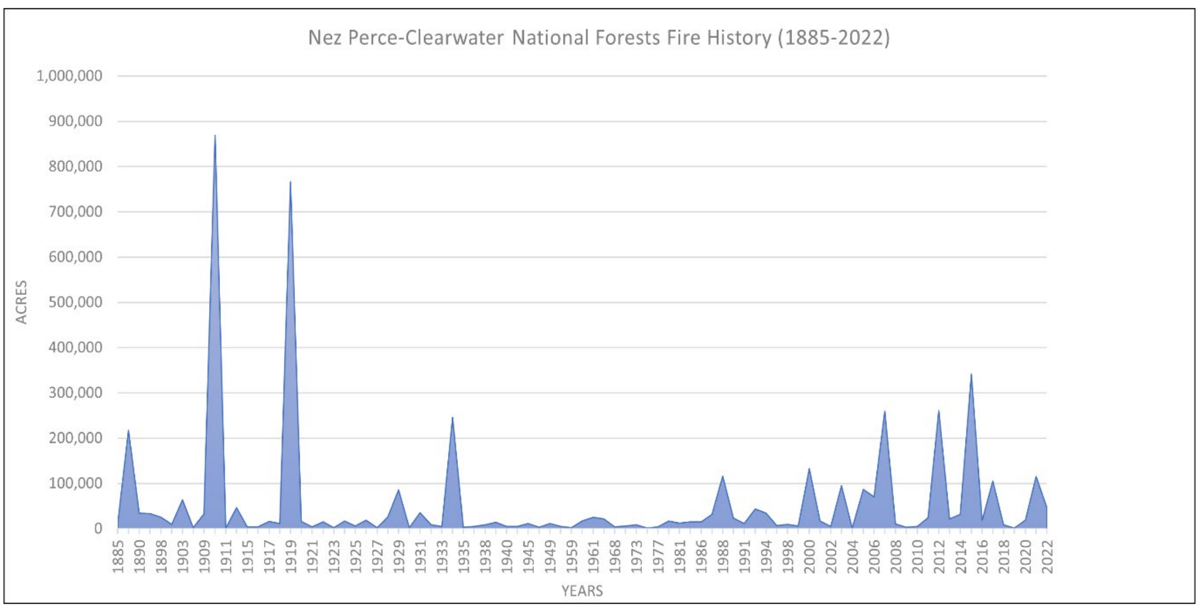

Figure 31. Historical Fire Acreage by year (1885–2022) in the plan area.

Data Source: FireStat and FACTS databases.

Recent increases in large fires can be attributed to climate change (Abatzoglou and Williams 2016), changes in national wildland fire policy since 1980, the recognition and implementation of allowing fire to play its necessary ecological role on the landscape, and the integration of the changing policy into the Nez Perce-Clearwater fire management program. Despite the recent trend of increased acreage since the late 1980s (Figure 31), the northern Rocky Mountains are still experiencing a fire deficit where acres burned historically have been less than what is expected and with longer fire rotations (Parks, Miller, et al. 2015).

Figure 32 displays the distribution of fire severity type within each of the five Historical Fire Regimes within the Nez Perce-Clearwater National Forests plan area from 1984–2021. This data suggests that in terms of fire severity, these regimes are functioning within their natural range. However, the amount of disturbance in terms of acres is significantly less than the desired amount (Table 98) within Fire Regimes I, II and III which represent 9.3, 0.44, and 53.8 percent of the plan area, respectively. These fire regimes are also within areas of the forest that are suitable for timber production and adjacent to the Wildland Urban Interface and other values at risk where fire suppression has been the most common fire management strategy deployed.

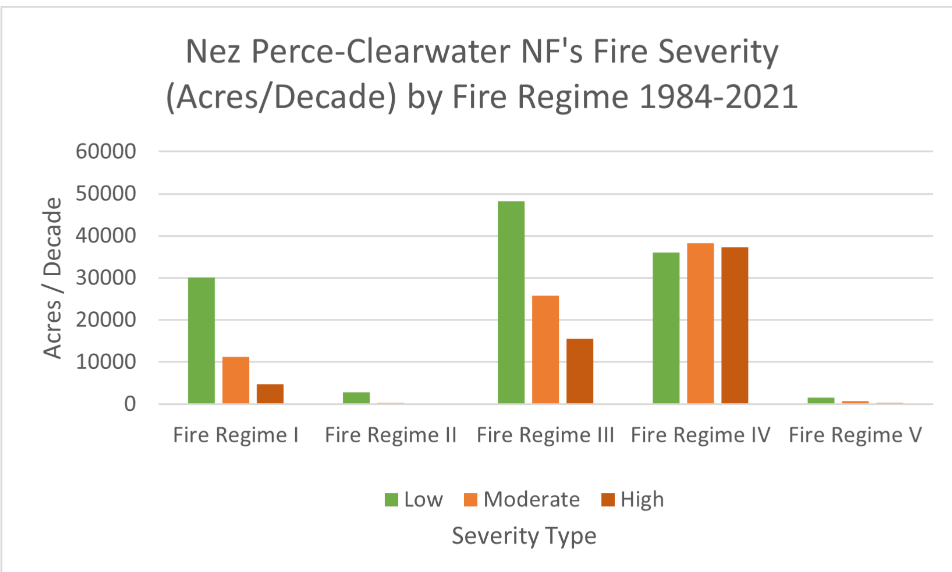

Figure 32. Fire Severity Acres by Decade from 1984 to 2021 within each of the five Fire Regimes within the Nez Perce-Clearwater National Forests Plan Area.

Data Source: MTBS and Landfire databases.

Fuels Treatments

The tools the Nez Perce-Clearwater has used to move towards desired conditions include hazardous fuel reduction by mechanical treatments, such as timber harvest and hand thinning; prescribed burning; and managing natural wildfire ignitions for resource objectives. Most of the mechanical fuels reduction and prescribed fire activities over the past ten years on the Nez Perce-Clearwater have been implemented as timber sales and reducing activity generated fuels resulting from harvest. Prescribed burning treatments have been undertaken to improve wildlife habitat in the forested and non-forested landscape where the forest plans have allowed those activities.

Timber harvest and associated slash disposal treatments such as pile burning, or broadcast burning of timber harvest activity fuels, has averaged 4,345 acres per year for the past ten years across the Nez

Perce-Clearwater and is expected to increase in pace and scale in the future. Hand thinning and other non-commercial mechanical treatments have accounted for approximately 2,510 acres per year over the past ten years. Wildland fire, including management ignited prescribed burning and wildfires managed to achieve land management plan objectives, has accounted for the majority of fuels treatment over the last ten years, with an annual average of 4,346 prescribed burning acres and 35,700 wildfire acres. Prichard et al. (2021) shows that intentional forest management is effective and corrective where practiced, however, the amount and location of fuels treatments and prescribed burning have not been enough to have had a significant effect in fostering fire resilient landscapes or reduce wildfire risk to communities (Kolden 2019).

Climate Change

Of all the ongoing and foreseeable future actions that have the potential to affect fire, especially unwanted wildfire, climate change is likely to be the single most important factor. As indicated by the vegetation composition over the centuries, the climate has fluctuated from cool and moist to warm and dry and has strongly been influenced by naturally occurring climate cycles, such as the 20- to 30-year Pacific Decadal Oscillation (PDO) and the 1- to 2-year El Nino Southern Oscillation (ENSO). These large-scale climate patterns influence the local climate across the Nez Perce-Clearwater by causing warmer or cooler and drier or wetter conditions depending on the phase of the Pacific Decadal Oscillation and El Nino Southern Oscillation (EcoAdapt 2014). Recently, an increase of minimum temperature has been more pronounced in the higher elevations, reducing snowpack and creating earlier spring melting and longer fire seasons. The changes associated with climate also contribute to changes in fire behavior characteristics and the corresponding fire frequency and severities within fire regimes for each of the broad potential vegetation types (Westerling et al. 2006, McKenzie et al. 2000). Since the 1980s, the increase in fire occurrence and extent have been influenced by warm springs and warm, dry summers, which drives the occurrence of regional-fire years throughout the Northern Rockies (Heyerdahl et al. 2001).

Historical weather data for the Nez Perce-Clearwater is represented by the United States Climate Division 4 Central Mountain area, which includes each of the counties that reside within the Nez Perce-Clearwater boundary. A comparison of weather parameters from 1885 to 1987 and 1988 to 2017 is one of the drivers that is associated with an increase in longer fire seasons and larger fires over the last 30 years. During this time, the combined annual mean temperature within these counties has seen an average annual increase of 1.42 degrees Fahrenheit and the combined mean annual precipitation has declined by 0.86 inches, per the National Oceanic and Atmospheric Administration's Climate Divisional Database[13].

Adapting landscapes to climate change and future wildfires will require more active management to open canopies of dry pine and moist mixed conifer species where fire resilient and larger size trees are favored. It will also require removing ladder fuels of smaller size class and fire intolerant tree species that compete for limited resources such as moisture, light, and growing space. Ultimately, promoting adaptation to climate change and future wildfire will require restoring landscapes to function within their historic fire regime (Hessburg et al. 2022).

Environmental Consequences

Effects to No Action Alternative

The current Nez Perce and Clearwater Forest Plans, as amended, are the existing management direction being used by the Nez Perce-Clearwater to address fire and fuels management. This direction represents the No Action Alternative. However, because the No Action Alternative is the baseline to which the Action Alternatives are compared, it is important to understand what actions would continue under the No Action Alternative.

The 1987 Nez Perce National Forest plan, as amended, will provide for resource protection and fire use necessary to protect, maintain, and enhance resource values and attain land management goals and objectives. The plan allows for the forestwide use of all management response options for wildfire such as control, contain, and confine. Exceptions for unplanned ignitions include Management Areas 7, 10, 12-15, 17, and 19-23. Planned prescribed fire is allowed forestwide. Mechanical treatments are not allowed in the Wilderness.

The Nez Perce National Forest Plan Amendment #34 allows fuel hazard reduction and watershed improvement activities in the Red River watershed concurrently with aquatic improvement activities if an upward trend is indicated.[14]

The 1987 Clearwater National Forest plan includes the following forestwide standard: fire strategies allow for the management of planned or unplanned ignitions to achieve a variety of resource objectives in many of the management areas. Wildfire strategies consist of confine, contain, and control objectives with maximum acres allowed to burn within each management area. Prescribed fire acres for natural and activity fuels were assigned for each management area. Recreation and research natural areas were not allowed to have unplanned ignitions and were only assigned contain wildfire strategies. Mechanical treatments are not allowed in the Wilderness.

Resource management would continue to occur at a similar pace and scale considering the appropriate management responses for each discrete management area within each plan. Wildland fire management would continue to use the full spectrum of responses to wildfire, as well as perform hazardous fuels treatment where and when appropriate. Most wildfires managed to achieve resource benefits would take place in the designated wildernesses or inventoried roadless areas. Wildfire suppression would be the primary strategy on fires that occur outside wilderness boundaries.

The majority of mechanical fuels reduction activities would be timber sales and the prescribed fire treatment acres, and emphasis would be treating activity fuels resulting from timber harvest residual slash. Fuels will continue to accumulate faster than management activities can treat them, resulting in an increased risk of losing key ecosystem components over time, especially in Fire Regimes I, II, and III.

Effects Common to Action Alternatives

Restoration and Maintenance of Fire Regimes

Natural, long-term variations in temperature and precipitation patterns, past management, and fire exclusion have resulted in continuously changing fire regimes (Whitlock et al. 2008) and, thus, continually changing forest conditions. This past climatic variability has had major effects on the timing, frequency, intensity, severity, and extent of wildfires, as would future changes in climate. The effect may be due to direct climate-related factors, such as increased temperature and greater drying of forest fuels,

[14] https://www.fs.usda.gov/detail/nezperceclearwater/landmanagement/planning/?cid=stelprdb5404075

or indirectly related to potential changes in forest composition and structure due partly to climate change. These climate-induced changes in fire regimes could have substantial impacts on ecosystems, with associated effects to communities and economies (Littell et al. 2009).

Restoring active fire regimes and reducing climate vulnerability requires managed wildfires that significantly thin forests, consume fuels, and favor fire-resistant, larger trees, or coupled mechanical thinning and prescribed or cultural burning treatment followed by regular maintenance burning (Prichard et al. 2021).

Wildfire has been, and will be, the greatest driver of vegetation change on the Nez Perce-Clearwater. Under all alternatives, natural unplanned wildfire would be allowed to play its ecological role. Along with prescribed fire, use of wildland fire will help in alleviating the fire deficit (Parks, Holsinger, et al. 2015, Vaillant and Reinhardt 2017), as well as providing many ecological benefits. Climate effects (Halofsky, Peterson, et al. 2018a, b), as well as plan components, that encourage the ecological role of fire will increase the amount of wildfire on the landscape under all revised plan alternatives.

The Forest Service manages wildfires to meet Land Management Plan desired conditions and resource objectives, using unplanned natural ignitions to achieve these objectives and ecological purposes to foster resilient ecosystems. The benefits of managing wildfires to meet resource objectives may include reducing fuels so that future fires burn in that area with lower severity (Parks, Holsinger, et al. 2015), increasing biodiversity (Martin and Sapsis 1991), cycling nutrients back into the soil (Hungerford et al. 1991), or reducing forest density to favor fire resistant species (Agee 1993). The increased use of unplanned ignitions in the revised plan alternatives would lead to greater fuels reduction and forest vegetation would be restored to more resilient conditions, which could mitigate climate change effects (Parks, Miller, Abatzoglou, et al. 2016) and help achieve the desired conditions.

From an ecological standpoint, fire should be allowed to serve its natural role. There are limited options for managing unplanned ignitions in proximity to human settlements and infrastructure, or in some cases where economic resource values are high (Noss et al. 2006). In all alternatives, fire suppression would continue to be an option for unplanned natural ignitions. Circumstances where wildfires are suppressed consider certain fuel and weather conditions, proximity to values at risk, time of year, or fire effects that are predicted to move the landscape away or not maintain desired conditions. Fire suppression may also be appropriate where rare or unique ecological values could be lost, such as imperiled species habitat where uncharacteristic fuel accumulations have created the potential for a fire that is outside the historical range of variability or where infrequent high severity fires are characteristic but where such fires are not viewed as ecologically desirable, such as old growth (Noss et al. 2006). These areas, as well as unburned areas or low severity burn areas within large mixed and high severity fires, could offer areas that are considered fire refugia. These areas are landscape elements that remain unburned or minimally affected by fire, thereby supporting postfire ecosystem function, biodiversity, and resilience to future disturbances. Fire refugia provide habitat for individuals or populations in which they can survive fire in which they can persist in the postfire environment and from which they can disperse into the higher-severity landscape (Meddens et al. 2018). However, when natural fires are suppressed in fire-adapted ecosystems, there could be detrimental effects to vegetation composition and structure, ecosystem processes, soil dynamics, wildlife habitat, and biodiversity of ecosystems (Keane et al. 2002). In combination with climate change, land-use change, and 20th century fire exclusion, suppression of wildfires also increases the existing fire deficit (Marlon et al. 2012). Fire suppression actions can also have direct negative impacts to resources (Ingalsbee 2004) and are sometimes ineffective at achieving objectives (Ingalsbee 2017).

Simulation modeling (SIMPPLLE) was used to estimate wildfire activity on the Nez Perce-Clearwater for five decades into the future. Best available information was used to build the fire logic and assumptions within the model, including corroboration with actual data, professional knowledge, and experience. Refer to Appendix B for a detailed discussion on model development and outputs. The model predicts that wildfire will continue to a similar degree under all alternatives, which equates to an average of approximately 587,500 acres per decade in forested vegetation types. The similarity across all alternatives is due to both natural and human caused ignitions, an expansive fuel source, and climate effects. It cannot be predicted with high accuracy where and when fires will occur. There is also a high degree of variation, both spatially and temporally, in the amount and location of fire.

Future Fuels Treatments

All alternatives contain desired conditions and objectives for treating vegetation through wildland fire and mechanical treatments to improve vegetative structure and composition. This includes reducing surface fuels, ladder fuels, and canopy density to reduce fire intensity. Additional benefits consist of minimizing impacts to values at risk and reducing fire spread to other ownerships. As of September 5, 2023, the Fuels Treatment Effectiveness Monitoring Database FTEM (firenet.gov) indicated there were at least 46 instances of wildfires interacting with previous mechanical and prescribed burning fuels treatments on the Nez Perce-Clearwater from 2018 to 2022. Most of these interactions documented the fire behavior being lessened when they breached the fuels treatment areas, often changing fire behavior from active or passive crown fire to surface fire. Wildfires that are documented in the FTEM database include Swan Boundary (2018), Grizzly (2019), Willow (2020), Shissler (2020), Crown (2021), BM Hill (2021), Snow Creek (2021), Fan (2021), Boulder Creek (2021), Dixie (2021), Larch (2022), Radcliff (2022), Wallow (2022), and Williams Creek (2022).

While mechanical treatments alone cannot fully mimic the ecological effects of fire, they are a valuable tool in creating stand structures that are more resilient to future disturbances (Schwilk et al. 2009). Prescribed fire and mechanical surrogates are generally successful in meeting short-term fuel reduction objectives and in changing stand structure and fuel beds such that treated stands are more resilient to high intensity wildfire (Stephens et al. 2012). Mechanical thinning of small stems and prescribed fire are effective techniques for restoring stand densities to levels that existed prior to fire exclusion, livestock grazing, logging, and plantation establishment within forests where low severity fires were most common (Noss et al. 2006).

In mixed-severity fire regimes where sufficient fire history information is available, a combination of thinning and prescribed fire might be used in restoration, yet only parts of these landscapes may warrant treatment because spatial variability is a hallmark of these landscapes. Hence, a landscape-level rather than a stand-level approach to restoration is warranted (Noss et al. 2006). Landscape-level treatment prescriptions that promote resilient patchworks with heterogeneous non-forest and forest ages can reduce the extent of high-severity wildfires and make landscapes less susceptible to extensive insect and disease outbreaks. Restoration of fire resilient mosaics in moist mixed-conifer forests, mixed conifer hardwood forests, fire-prone deciduous forests (for example, aspen), and cold forests is also needed (Prichard et al. 2021).

Fire exclusion and past management activities may have had little impact on high severity fire regimes (Westerling et al. 2006). Research following large fires within these fire regimes showed fuels treatments, such as mechanical thinning and prescribed fire, can be successful at protecting values at risk from subsequent fire even during extreme fire behavior (Graham et al. 2009). Locally on the Nez Perce-Clearwater National Forests, The Orogrande Community Protection Project was signed in 2016 and implementation began in 2017. The project consisted of harvest adjacent to the private property, non-commercial thinning along the main access road, and prescribed fire. The commercial harvest and non-commercial thinning activities were completed and the activity fuels from harvest were burned prior to the start of the Williams Creek fire in August 2022. This fire started in the Gospel Hump Wilderness and initial response was to suppress. Considerable effort and dedication of resources to the fire proved to be ineffective and responders switched to the strategy of point protection for the town of Orogrande. On September 8th, the fire burned 3 miles and the flaming front hit the fuels treatments and went around and over the top of the community. Some structures were damaged and some lost, however, fire managers stated that had the fuels treatments not been there to break the continuity of fuel into the community that there would have been significantly more loss and damage to infrastructure within the community of Orogrande.

Prescribed fire is essential to reducing fuels. It is possible to craft treatments to achieve both ecological restoration and fire hazard reduction (Reinhardt et al. 2008). However, ecological restoration will also include reintroducing fire and other active management. Additionally, the most effective ecosystem treatments should include prescribed fire. Prescribed fire on the landscape in all alternatives would be expected to partially offset predicted effects from climate change (Wiedinmyer and Hurteau 2010). Prescribed fire is essential to reducing fuels. It is possible to craft treatments to achieve both ecological restoration and fire hazard reduction (Reinhardt et al. 2008). However, ecological restoration will also include reintroducing fire and other active management. Additionally, the most effective ecosystem treatments should include prescribed fire. Prescribed fire on the landscape in all alternatives would be expected to partially offset predicted effects from climate change (Wiedinmyer and Hurteau 2010).

Fire Management Flexibility

Key considerations for fire management are described in this section. A large number of burnable acres of National Forest System lands cannot be actively managed by mechanical means. Additionally, mechanical treatments in designated wilderness are limited, except as necessary, to meet the minimum needs for protection and administration of the area as wilderness. Administrative use of motorized equipment is allowed in recommended wilderness. Appropriately managing wildfire in places with an opportunity to obtain resource benefits and a low risk of potential damages may be the only way in many areas to increase the pace and scale of ecosystem restoration activities. Informed management of wildfire would also be needed to maintain areas once restoration has occurred. Wildland fire also exhibits self-regulating effects where a burned area will act as a fuel break and reduce the probability of subsequent fire spread (Parks, Holsinger, et al. 2015). This effect is dependent upon many factors, including vegetation type, previous burn severity, and climate but can be reduced by climate-induced extreme weather events (Parks, Miller, Abatzoglou, et al. 2016) which are predicted to be more common in the future (Westerling et al. 2011).

The alternatives vary from the fuels management perspective on the allocation of acres and different designated areas; the primary designated area that impacts fuels management is recommended wilderness. Other management limitations apply to all alternatives. In inventoried roadless areas, which comprise most recommended wilderness areas, there are limitations on road construction and timber cutting relating to the purpose and location of treatments in relation to identified wildland urban interface. Additionally, the implementation of the Northern Rockies Lynx Management Direction (U.S. Department of Agriculture 2007f) constrains treatments in lynx habitat outside the wildland urban interface where multi-storied hare habitat or stand initiation hare habitat is present.

The use of prescribed fire within the wildland urban interface is a high-risk action and is often more expensive than prescribed fire in the non-wildland urban interface. This is due to the extra steps taken to ensure public safety and mitigate hazards to private property. Additionally, impacts from smoke emissions adjacent to homes for extended periods limit the number of acres that can be treated. Within the wildland urban interface, there is an increased need to rely on mechanical and hand treatments rather than fire. In addition, social issues, such as the effects of treatments on scenery, air quality, noise, and wildlife viewing, can be more contentious.

Effects that Vary by Alternatives

Future Fuels Treatments

In all alternatives, mechanical fuels reduction and prescribed fire would continue to be used to move vegetation on the Nez Perce-Clearwater toward desired future conditions. Mechanical treatments, including harvest, can be used to achieve fuel management objectives, such as reducing forest densities and favoring fire-resistant species, but effectiveness is dependent upon harvest type and subsequent slash disposal (Hartsough et al. 2008). Mechanical treatments are often more effective when combined with prescribed fire to reduce surface fuels. Mechanical plus burning treatment produces stand structures with fewer ladder fuels (saplings) and lower rates of fuel accumulation (that is, fewer snags that remain to fall and less twig and litter fall from live trees due to reduced basal area), leading to more rapid development of conditions resilient to wildfire (Schwilk et al. 2009). Treatment of surface fuels through prescribed fire has shown to reduce surface fire intensity, flame lengths, and convective and radiative heating and contributed to lower postfire mortality than thin only treatments in mixed conifer forest (Prichard et al. 2010). Relative to impacts to fire management, treatments that may occur in the wildland urban interface may be the most important for protecting values at risk. Each alternative should emphasize treatments inside the wildland urban interface. The amount of anticipated mechanical treatments within forested areas varies by alternative (Table 99). The current plans would treat the fewest acres followed by Alternative Z. Alternatives W, X, Y, and the Preferred Alternative are projected to result in similar acres being treated mechanically. The Preferred Alternative would result in the most acres treated, consistent with the theme of this alternative, meeting vegetative desired conditions in 30–35 years. The No Action Alternative is projected to result in the least mechanical treatments within forested vegetation types. Additional potential treatments in non-forested vegetation types are not reflected in the projections but may be necessary to facilitate prescribed burns to achieve desired conditions.

Table 99. Estimated average mechanical treatment acres per decade over 50 years by alternative.

No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
43,450[1]	155,767	155,935	149,904	84,552	159,255

Acres are from the PRISM model and only include forested areas. Non-forested area is not included in these figures. Calculations include areas both inside and outside the wildland urban interface.

[1]Acres of mechanical fuels treatment over the past 10 years under the current plans.

In all alternatives, prescribed fire would continue to be used to move the Nez Perce-Clearwater towards desired future conditions. The amount of anticipated prescribed fire within forested areas varies by alternative (Table 100). These acres do not account for site prep or brush disposal burning associated with timber harvest as identified in Table 99. These are landscape burns implemented to achieve the desired vegetative conditions. The No Action Alternative is projected to result in the fewest acres treated with landscape prescribed fire, followed by Alternative Z. Alternative X is projected to result in the most acres treated to meet vegetative desired conditions in 20 years. Additional potential treatments in non-forested vegetation types are not reflected in the projections but may be necessary to achieve desired conditions in all alternatives.

Table 100. Estimated average prescribed fire acres per decade over 50 years by alternative.

No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
55,600[1]	73,449	83,320	80,171	64,505	67,987

Acres are from the PRISM model and only include forested areas. Non-forested area is not included in these figures. Calculations include areas both inside and outside the wildland urban interface.

[1]Acres of prescribed fire treatment over the past 10 years under the current plans, includes non-forested treatments.

Fire Management Flexibility

The alternatives vary from the fuels management perspective on the allocation of acres to different designated areas. The primary designated area that impacts fuels management is recommended wilderness due to limitations on mechanical treatments. However, most recommended wilderness areas are inventoried roadless areas, which would already limit mechanical treatments due to constraints on road building and access. This is most important where recommended wilderness overlaps with wildland urban interface where it is assumed that the majority of fuels mitigation would occur. Due to the objectives of fuels treatments, such as reducing canopy density and ladder and ground fuels, fuels treatments in the wildland urban interface would produce vegetation structure that is most likely not compatible with wilderness characteristics, especially in higher elevation vegetation types. Due to this constraint, wildland urban interface mechanical fuels treatments within recommended wilderness would be very limited as they would not meet their purpose and need and could be ineffective.

Within recommended wilderness, wildfire would primarily be used to meet resource objectives, with less emphasis on mechanical treatments and prescribed fire. However, fuels management would be dependent upon the use of unplanned ignitions and the risk assessment associated with each season and event that may require suppression actions instead. Due to constraints on mechanical treatments, there would be limited opportunities to pretreat areas that would serve as buffers for naturally ignited wildfires and the ability to use wildfire for resource benefit would likely be reduced. The location of the ignition would weigh heavily on decisions relating to suppression or long-term management of a given fire.

Fuels treatments and wildland fire within the suitable Wild and Scenic River lands could be used if they adhere to maintaining, enhancing, or protecting the outstandingly remarkable values, free flowing characteristic, or water quality for which the river was designated. These protections may or may not be compatible with some fuels treatment methods. Table 101 displays total acres of recommended wilderness and the eligible and suitable Wild and Scenic rivers by alternative.

Table 101. Acres of recommended wilderness and eligible and suitable Wild and Scenic Rivers by alternative.

Area	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Recommended Wilderness	197,695	856,932	0	309,332	569,755	258,210
Wild and Scenic eligible and suitable lands	155,477	74,646	0	110,252	166,176	61,849

Alternative W would have the most acreage of recommended wilderness compared to the other alternatives and the second least acreage within eligible and suitable Wild and Scenic rivers. Based on land allocations, this alternative provides the least flexibility for fire management, resulting in the fewest opportunities of mechanical fuels treatments. With less flexibility in conducting associated fuel management activities, unplanned natural ignitions may require suppression actions and desired conditions may not be met.

Alternative X provides the most flexibility for fire management by including no recommended wilderness or eligible and suitable Wild and Scenic rivers, resulting in the greatest opportunities for mechanical treatments and prescribed fire, which could lead to more opportunities to effectively use future natural unplanned fires for desired conditions.

Alternative Y has more recommended wilderness and the second most acres of eligible and suitable wild and scenic rivers than the current plans and would offer less flexibility than the current plans to meet desired conditions.

Alternative Z would be like Alternative W except there would be fewer acres of recommended wilderness and the most acres of eligible and suitable Wild and Scenic rivers. This may result in reduced flexibility for unplanned natural ignitions used to meet the revised plan desired conditions and the least flexibility to use mechanical fuels reduction methods to achieve desired conditions.

The Preferred Alternative has slightly more acres of recommended wilderness as compared to the current plans. It also has the least amount of eligible and suitable wild and scenic river acres. Of all the revised plan alternatives, except for Alternative X, which has no acres of recommended wilderness or eligible and suitable wild and scenic river acres, this alternative provides the most flexibility for the greatest number of fire management activities to meet desired conditions.

Cumulative Effects

Human Population Increases and Shifts towards Wildland Urban Interface

More human development is occurring near the boundary of lands administered by the Nez Perce-Clearwater. This trend is expected to continue in the future and is likely to have effects on forest vegetation. The need for vegetation treatments being implemented within wildland urban interface areas will increase. The objective is to reduce hazardous fuels, as well as conduct fewer vegetation treatments, in areas located away from communities. To work individually with property owners is costly and creates a patch work of defendable properties among those that are not. In addition, the types of fuel treatments used in the wildland urban interface are often more expensive than methods elsewhere and social issues, such as the effects of treatments on scenery, air quality, noise, and wildlife viewing, can be more contentious. Therefore, higher public involvement, planning, and implementation expenses are likely to lead to fewer acres being treated within a given budget level. The ability for fire managers to implement prescribed burns will lessen in the wildland urban interface Despite efforts to suppress human-caused fires, these types of fires are more likely in the wildland urban interface as more people live and recreate in the area.

The wildland urban interface has become the focus of wildland fire suppression resources. The future increase in the wildland urban interface will continue to challenge wildfire management during large fire events as “firefighters will likely have to protect dispersed housing over an extremely large area of fire-prone forest” (Gude et al. 2008).

Relative to current levels, more wildfire in the future is expected and policies that foster adaptive resilience in the wildland urban interface (WUI) are needed (Shoennagel et al. 2016). Building homes with fire-resistant materials and landscaping will reduce ignitability and result in fire-resilient properties capable of withstanding future fires (Cohen 2000). This is consistent with Goal 2 of the National Cohesive Wildland Fire Management Strategy that targets creating fire adapted communities, which is primarily the responsibility of private landowners and local and state governments. While the Forest Service cannot directly engage in any private structural fire, strategy and tactics are used to prevent a wildland fire from reaching private structures (U.S. Department of Agriculture 1991). The other two goals of the National Cohesive Wildland Fire Management Strategy are for restoring and maintaining landscapes and wildfire response, which is the focus of forest service fire management. By working together across boundaries, all three goals can come together to better facilitate managing wildland fire on the landscape in closer proximity to the wildland urban interface. Treating dry and moist mixed-conifer forests beyond WUI buffers can modify fire behavior and change the intensity of wildfires arriving at communities.

Increased Regulation and Concern over Smoke Emissions

The ability to use fire to maintain and restore the fire-adapted ecosystems on the Nez Perce-Clearwater or to reduce hazardous fuels in the wildland urban interface is dependent upon air quality regulations. As air quality regulations become stricter, the ability to use prescribed fire as a management tool becomes limited. If past trends of increasing regulations and decreasing burn opportunities continue, the effects would likely result in not being able to use fire enough to make meaningful improvements to forest and fuel conditions and meet objectives.

Timber Product Manufacturing Infrastructure and Economics

The ability of the Nez Perce-Clearwater to positively affect forest vegetation is partially dependent upon the ability to sell forest products and to use harvesting process, including the residual slash disposal activities to positively affect the forest vegetation and reduce hazardous fuels. If the forest products industry declines in areas surrounding the Nez Perce-Clearwater to the degree that it is difficult to sell forest products, or if "stumpage prices" decrease substantially, it would affect how many acres could be treated. While some treatments could be accomplished by using prescribed burning only, it is generally very risky in the wildland urban interface and expensive, leading to fewer acres treated.

Other Plans

Since they were developed, national level plans, initiatives, and acts, such as the National Fire Plan, Healthy Forest Initiative, Healthy Forest Restoration Act, and National Cohesive Wildland Fire Management Strategy, have influenced the vegetation and fuel management programs on the Nez Perce-Clearwater. Therefore, they have had some effects on hazardous fuels and it is anticipated that they will continue to do so for the foreseeable future. In general, these plans have resulted in more vegetation treatments being implemented near wildland urban interface areas with the objective of reducing hazardous fuels and vegetation treatments in areas located away from communities. Not only do these plans emphasize the need to reduce hazardous fuels in the wildland urban interface, but they also stress the need to restore the natural fire regimes and forest conditions to the larger national forest landscape. These plans encourage the development of more resistant and resilient forest vegetation that would be less susceptible to large undesirable wildfires and insect outbreaks.

Portions of the Nez Perce-Clearwater adjoin other national forests, each having its own forest plan or land management plan. The Nez Perce-Clearwater is also intermixed with lands of other ownerships, including private lands, other federal lands, and state lands. Some adjacent lands are subject to their own resource management plans. The cumulative effects of these plans, in conjunction with the Nez Perce-Clearwater Land Management Plan, are summarized below for those plans applicable to fire management.

The forest plans or land management plans for National Forest System lands adjacent to the Nez Perce-Clearwater include the Payette, Wallowa Whitman, Idaho Panhandle, Lolo, and Bitterroot National Forests. All plans address fire management and generally are consistent across all national forests due to law, regulation, and policy. The cumulative effect would be that the management of fire and fuels would be generally complementary. This includes specific adjacent landscapes that span national forest boundaries, such as the Selway-Bitterroot and Frank Church River of No Return Wilderness areas, Hells

Canyon National Recreation Area, Rapid River Wild and Scenic River, Mallard-Larkin Pioneer Area, and the Salmon River.

Other adjacent federal lands are administered by the Bureau of Land Management and the United States Army Corps of Engineers. The Cottonwood Field Office of Bureau of Land Management has Resource Management Plans that were signed in 2009 for lands near the Nez Perce-Clearwater. The United States Army Corps of Engineers has the Dworshak Master Plan that was signed in 2015. These plans contain components related to fire and fuels and would likely be complementary to Nez Perce-Clearwater plan components.

The Idaho Department of Lands Fire Management Plan guides fire management on state lands in Idaho. The plan includes concepts that are complementary to revised plan components for the Nez Perce-Clearwater, such as state direction for suppression of wildfires. While specific desired conditions are not stated in the same terms as the Nez Perce-Clearwater, it is likely that some elements, such as providing for firefighter and public safety, would be similar. State forestlands may be actively managed to a greater degree than National Forest System lands and would likely contribute to achievement of some desired fire and fuels conditions across the landscape. The Idaho State Wildlife Action Plan describes a variety of vegetation conditions related to habitat for specific wildlife species. These plans would likely result in the preservation of these habitats on state lands, specifically wildlife management areas. The vegetation conditions described would be complementary to the conditions being managed for in the revised Nez Perce-Clearwater Land Management Plan.

Some county wildfire protection plans map and define the wildland urban interface. The Forest Service notes that these areas may be a focus for hazardous fuels reduction. Other plan components, such as Northern Rockies Lynx Management Direction, have guidance specific to these areas. Managing for more open forests of large diameter fire resilient species may be particularly emphasized in these areas. Overall, the effect of the county plans would be to influence where treatments occur to contribute to desired vegetation conditions.

Effects to Resource from Other Resources

Air Quality

The consequences to fire from air quality are the same for all alternatives. All alternatives have the same plan components to meet air quality standards established by federal and state agencies. The Forest Service would meet the requirements of state implementation plans and smoke management plans. Laws and regulations on smoke emissions can limit opportunities to conduct prescribed burning. These limitations are most frequently encountered in high population density areas.

Climate Change

As climate changes, the number of large, severe fires could continue to increase. Many of these ecosystems that historically burned under low to mixed severity are now burning with higher severities. Climate changes could also reduce the potential for some species to naturally regenerate and increase the potential for more disturbance-adapted species that could reduce the resiliency of ecosystems. The current and potential increase of fire frequency and severity could also increase water temperatures, increase sedimentation, and alter or loss of wildlife habitat (EcoAdapt 2014). Adapting landscapes to climate change and future wildfires will require more active management to open canopies of dry pine and moist mixed conifer species where fire resilient and larger size trees are favored. It will also require removing ladder fuels of smaller size class and fire intolerant tree species that compete for limited resources such as moisture, light, and growing space. Ultimately, promoting adaptation to climate change and future wildfire will require restoring landscapes to function within their historic fire regime (Hessburg et al. 2022).

Livestock Grazing

In all alternatives, livestock grazing would occur on portions of the Nez Perce-Clearwater. Plan components would enable grazing activities to complement fire management, such as reducing fine fuels to lower fire risk. However, grazing can alter grassland and shrubland fire regimes through soil disturbance, increased competition from non-native annual grasses, and reduction in fine fuels (Knick et al. 2005). Duration and intensity of grazing could affect prescribed fire implementation by reducing available fuels. Location and timing of grazing could also affect prescribed fire implementation by restricting available burn units. Coordination with affected grazing allotment permittees should occur for all fuels treatments to meet objectives.

Timber

Consequences from timber management for all alternatives could complement fuels management by reducing fuel loads and increasing resilient landscapes. Vegetation treatments would need to be designed and implemented to achieve multiple resource social and economic objectives, as well as those associated with fuels management. However, there are differences with the number of acres of timber harvest activity within each of the action alternatives. Timber harvest treatments in conjunction with prescribed fire could help moderate fire behavior and will help to reduce the overall risk to resources and communities. All alternatives also recognize that not all fire is detrimental to timber production. Therefore, there is opportunity to allow wildfires to burn to help maintain and restore fire adapted ecosystems.

Watershed, Soil, Riparian and Aquatic Management

Plan components recognize that wildland fire, along with mechanical fuels treatments, will play a key role in maintaining and restoring watersheds and riparian ecosystems. Consequences from these components would be generally similar for all alternatives. However, in order to meet the plan direction associated with these resources there could be occasions where prescribed fires or mechanical treatments cannot be used if there are potential negative effects to aquatic and riparian-associated resources. Fuels management activities occasionally require some soil disturbing activities or road construction, which may be limited to meet other plan components. Although it is difficult to quantify the effects, all the alternatives have components that would limit fire or fuels treatments for ecosystem maintenance or restoration.

All alternatives would contain components that limit equipment use on steep slopes. However, the revised plan alternatives also include guidelines that require a minimum amount of organic matter to be present following treatments, which may be difficult to achieve following prescribed fire in some cases. The revised plan alternatives also contain guidelines for the retention of snags and coarse woody debris, which would also factor in to prescribed burning prescriptions. Finally, the revised plan alternatives include the adoption of riparian management zones, which are similar in size to the riparian zones currently identified on the forest. The plan components associated with riparian management zones would also influence fuels treatments and fire suppression actions to ensure minimal impacts and ecological benefits.

In summary, all alternatives include plan components for the protection of water, soil, and aquatic resources. The components for the revised plan alternatives are similar to those in the current plans.

Wildlife

In general, wildlife management direction has low impact on fire risk, fire management, and ecosystem resiliency to fire. The management direction recognizes the importance of managing vegetation for fuels reduction and vegetation structure and composition across the Nez Perce-Clearwater that is consistent with natural range of variation.

The Northern Rockies Lynx Management Direction (U.S. Department of Agriculture 2007f) recognized the importance of fuel treatments within the wildland urban interface as designated by the Healthy Forest Restoration Act. However, opportunities to conduct vegetation treatments, including prescribed fire or mechanical fuels reduction treatments, outside the wildland urban interface are limited under current lynx management direction. The restrictions on treatments within these forest conditions are likely to reduce the ability and effectiveness of achieving desired forest and fuel conditions outside the wildland urban interface, for reasons summarized below.

Restrictions from lynx management direction on treatment in multistory hare habitat and young seedling and sapling forests have the greatest impact. These forest conditions are widespread in the plan area due to dominant subalpine fir and spruce forest, as well as using fire as a natural disturbance process to create large areas of seedling and sapling forest. Thinning of dense sapling stands is typically designed to create future forests composed of larger trees and desired species such as fire resistant Western larch. These forests are more resilient in the face of future wildfire events and may burn less severely, reducing potential future impacts to values at risk. Thinning in most dense seedling and sapling stands outside the wildland urban interface is not allowed under current management direction. Treatments in multi-story forests that provide hare habitat that would result in it no longer qualifying as multi-story hare habitat is also not allowed outside wildland urban interface, thereby limiting the Nez Perce-Clearwater’s ability to manage landscape patterns and fuel conditions across some portions of the Nez Perce-Clearwater to achieve desired conditions. The use of unplanned wildfire ignitions to achieve desired conditions is frequently infeasible due to seasonal changes in weather and fuel conditions.

Conclusion

Fire is a critical ecological function that plays a central role in providing quality habitat for both plant and wildlife species. Table 102 contains a summary of annual fire management consequences by alternative. All alternatives would ensure fire remains a part of the ecological system and would move the Nez Perce-Clearwater towards desired future conditions. This is achieved through a variety of management actions, including wildland fire and mechanical treatments.

Table 102. Potential consequences to annual fire management (in acres), by alternative.

Measurement Indicator	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Restoration and Maintenance of Ecological Role of Fire/Year[1]	35,700[2]	35,828	34,825	35,742	43,844	36,026
Future Fuels Treatments/Year	9,905	22,922	23,925	23,008	14,906	22,724
Fire Management Flexibility[3]	353,172	931,578	0	419,584	735,931	320,059

[1]Unplanned natural fire managed to meet forest plan desired conditions and objectives.

[2]Acres of unplanned fire managed for resource benefit over the past 10 years under the current plans.

[3]Denotes acres of special management considerations, such as recommended wilderness and suitable wild and scenic river designation, where certain treatments may not be allowed.

Future wildfire and fire regimes: The projected levels of future wildfire, and their subsequent impact on fire regimes, are generally the same across alternatives because vegetation over time is generally the same for all alternatives and projected future treatments are also similar. Factors such as climate have a greater bearing on vegetation change and potential wildfire activity than active management.

Future fuels treatments: The No Action Alternative would achieve the least amount of fuel reduction and prescribed fire in forested areas, followed by Alternative Z. This is due to the projection of meeting vegetative desired conditions in 100 years. Alternatives W, X, Y, and the Preferred Alternative would treat similar amounts of acreage over the course of the plan. All alternatives would tend to treat more acres than the current plans. Alternative X would treat the most acres due to the projection of meeting desired conditions in the shortest amount of time. However, other factors affect the number of acres treated to meet the revised plan desired conditions relating to fire and fuels management. Some of these factors include budget allocation, climate and seasonal weather variation, and wildfire occurrence. Budget has direct affects to the extent the National Forest can treat mechanically and with prescribed fire. Climate and seasonal weather variation affect the ability to conduct prescribed burns. Wildfire activity requires the use of personnel and other resources that would be used for implementing mechanical and prescribed fire treatments.

Flexibility for fire management: Different management designations, specifically recommended wilderness, affect where management tools, such as mechanical treatments, can be used. The current plans and Alternatives W, Y, Z, and the Preferred Alternative would all limit mechanical treatment options within recommended wilderness areas and eligible and suitable wild and scenic river areas, with Alternative Y having the most area restricted. If these areas became designated wilderness or designated Wild and Scenic rivers, then additional constraints on treatments would exist. Alternative X has the greatest flexibility for fire and fuels management, followed by the Preferred Alternative, the current plans, and Alternatives Y, Z, and W.

3.2.5 Invasive Species

This section addresses invasive species management. The mission of the Forest Service is to sustain the health, diversity, and productivity of the nation's forests and grasslands to meet the needs of present and future generations. Invasive species are among the most immediate environmental and economic threats facing the Nation's forest, grassland, and aquatic ecosystems, endangering native species and threatening ecosystem services and natural resources (U.S. Department of Agriculture 2013a).

A species is considered to be invasive if it meets two criteria: 1) it is non-native to the ecosystem under consideration, and 2) its introduction causes, or is likely to cause, economic or environmental harm, or harm to human, animal, or plant health (Executive Order 13571). Invasive species include all taxa, including plants, vertebrates, invertebrates, and pathogens.

An invasive species can drastically modify or disrupt the ecosystem it colonizes. Although invasive species often adapt to habitats where they are not native, they lack the natural controls, such as predatory insects and disease, that may have evolved with them within their native ranges. As a result, they tend to spread aggressively and reduce overall native community diversity and generally disrupt the natural processes of the environment. Invasive species displace native species, reduce forage for some animal species, degrade natural communities, change hydrology, change microclimatic features, increase soil erosion, alter wildfire intensity and frequency, and cost land management agencies millions of dollars in treatments (U.S. Department of Agriculture 2001a). Invasive species concerns on the Nez Perce-Clearwater are primarily associated with invasive terrestrial and aquatic plants and aquatic invertebrates. Invasive plants can compete and displace desirable native vegetation, alter effective ground cover, and disrupt natural ecological processes. Aquatic invasive species are non-native plants, animals, and microorganisms living in aquatic habitats that have the potential to impair aquatic ecosystem conditions.

Changes Between Draft and Final

Comments received since the publication of the proposed action and Draft Environmental Impact Statement have been used where appropriate to improve the Land Management Plan and have helped inform the Final Environmental Impact Statement. An additional goal was added to emphasize working with other agencies, groups, and adjacent landowners to support integrated invasive species management. The desired conditions were consolidated with more focus on retaining ecosystem resilience and biodiversity. Multiple minor changes were made in the Final Environmental Impact Statement; all changes are within the scope of the Draft Environmental Impact Statement analysis and address issues that the public had an opportunity to comment on. As a result of public input, an additional alternative was developed. The Preferred Alternative is a compilation of portions of the other alternatives analyzed in detail in the Draft Environmental Impact Statement. Analysis of the Preferred Alternative for invasive species is similar to the other action alternatives.

Relevant Laws, Regulations, and Policy

Federal Laws

Federal Insecticide Fungicide and Rodenticide Act of 1947, as amended (Pub. L. 92-516): This act requires all pesticides to be registered with the Environmental Protection Agency. It also states that it is unlawful to use any registered pesticide in a manner inconsistent with its labeling.

Carlson-Foley Act of 1968 (Pub. L. 90-583): This act authorizes and directs the heads of Federal departments and agencies to permit control of noxious plants by state and local governments on a reimbursement basis in connection with similar and acceptable weed control programs being carried out on adjacent non-federal land. In other words, this act permits county and state officials to manage noxious weeds with herbicides on federal lands and to be reimbursed for that management, given that other applicable laws, such as the National Environmental Policy Act are also met.

Federal Noxious Weed Act of 1974, as amended (Pub. L. 106-224): This act states that each federal agency shall establish and adequately fund an undesirable plant management program, complete and implement cooperative agreements with state agencies regarding the management of undesirable plant species on federal lands under the agency's jurisdiction, and establish an integrated management system to control or contain undesirable plant species targeted under cooperative agreements.

Federal Land Policy and Management Act of 1976 (Pub. L. 94-579): This act provides authority to federal agencies to control weeds on rangelands as part of a rangeland improvement program.

National Invasive Species Act (NISA): This act was passed in 1996 amending the Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990. It includes regulations to prevent the introduction and spread of aquatic invasive species from entering inland waters through ballast water carried by ships and other watercraft, the development of state management plans and regional panels to combat the spread of aquatic nuisance species, and additional aquatic nuisance species outreach and research.

Plant Protection Act of 2000: This act consolidates and modernizes all major statutes pertaining to plant protection and quarantine, including the Federal Noxious Weed Act and the Plant Quarantine Act, and permits the Animal and Plant Health Inspection Service to address all types of weed issues. It also authorized the Animal and Plant Health Inspection Service to take both emergency and extraordinary emergency actions to address incursions of noxious weeds.

Executive Orders

Executive Order 13112 (Feb. 3, 1999): This order directs federal agencies to prevent the introduction of invasive species, detect and respond rapidly to and control populations of such species in a cost-effective and environmentally sound manner, to monitor invasive species populations accurately and reliably, to provide for restoration of native species and habitat conditions in ecosystems that have been invaded, to conduct research on invasive species and develop technologies to prevent introduction, to provide for environmentally sound control of invasive species, and to promote public education on invasive species and the means to address them. All of these actions are subject to the availability of appropriations (Clinton 1999).

Executive Order 13751 (Dec. 8, 2016): Safeguarding the Nation from the Impacts of Invasive Species: This order Amends EO 13112 and directs coordinated Federal prevention and control efforts related to invasive species; incorporates considerations of human and environmental health, climate change, technological innovation, and other emerging priorities into Federal efforts to address invasive species; strengthens coordinated, cost-efficient Federal action; and revises several definitions.

National Forest System Policy

Forest Service Manual 2900 - Invasive Species Management: This policy ensures that forest management activities are designed to minimize or eliminate the possibility of establishment or spread of invasive species on National Forest System lands or to adjacent areas (U.S. Department of Agriculture 2011a). The Manual mandates management activities for aquatic and terrestrial invasive species (including vertebrates, invertebrates, plants, and pathogens) will be based on an integrated pest management approach on all areas within the National Forest System, and on areas managed outside of the National Forest System under the authority of the Wyden Amendment (P.L. 109-54, Section 434), prioritizing prevention and early detection and rapid response actions as necessary.

Forest Service Manual 2070 - Vegetation Ecology: This policy provides direction for the use of native and non-native seed use on National Forest System lands. It specifically emphasizes the use of native seed mixes in all revegetation, rehabilitation, and restoration projects on National Forest System lands.

Forest Service Manual 2150 - Pesticide Use Management and Coordination: This policy provides direction on the use of pesticides as part of an integrated pest management approach. Additional guidance is provided in the Pesticide Use Management Handbook (FSH 2109).

State and Local Law

Idaho Invasive Species Act of 2008: This act provides policy direction, planning, and authority to combat invasive species infestations throughout the state and to prevent the introduction of new species that may be harmful.

Idaho Code Title 22 Chapter 24 - Noxious Weeds: This law defines State of Idaho noxious weeds and identifies landowner and agency responsibilities and penalties for violations. It also establishes Weed Control Advisory Committees and authorized cooperative agreements.

Idaho Department of Agriculture, Rule 02.06.09 - Rules Governing Invasive Species and Noxious Weeds: This rule governs the designation of invasive species, inspection, permitting, decontamination, record keeping, and enforcement and applies to the possession, importation, shipping, transportation, eradication, and control of invasive species. The rule also identifies those noxious weeds which have been officially designated by the Idaho Department of Agriculture Director as noxious weeds in the State of Idaho, designates articles capable of disseminating noxious weed, requires treatment of articles to prevent dissemination of noxious weeds, and provides the authority to designate cooperative weed management areas for the management of noxious weeds. In addition, this rule governs the inspection, certification, and marking of noxious weed free forage and straw to allow for the transportation and use of forage and straw in Idaho and states where regulations and restrictions are placed on such commodities.

Other Regulation, Policy, and Guidance

Forest Service National Strategic Framework for Invasive Species Management of 2013: This framework provides broad and consistent strategic direction on the prevention, detection, and control of invasive species. This policy directs the Forest Service to 1) determine the factors that favor establishment and spread of invasive plants; 2) analyze invasive species risks in resource management projects; and 3) design management practices that reduce these risks.

National Road Map for Integrated Pest Management, Revised September 2018: The goal of the National Road Map for Integrated Pest Management is to increase the adoption and efficiency of effective, economical, and safe integrated pest management practices. The Road Map is intended to be updated periodically by the Federal Integrated Pest Management Coordinating Committee.

Annual National Forest Service Invasive Species Program Management Program Direction and Business Area Requirements: This document provides National Forest System invasive species management program direction and business areas for the management of all aquatic and terrestrial invasive species on all National Forests and Grasslands and on adjacent areas under the provisions of the Wyden Amendment. It provides annual guidance on work activity planning, record keeping, and reporting and program performance.

Region One Weed Free Forage and Mulch Order: The purpose of this order is to restrict the introduction or spread of noxious weeds on National Forest System lands. The order prohibits possessing, storing, and transporting straw, hay, grain, seed, or other forage or mulch product without proper documentation and markings by a State of Idaho certification program that meets or exceeds the North American Weed Free Forage standards.

Methodology

The quantitative analysis focuses on invasive plants. Other invasive species are analyzed qualitatively due to lack of quantitative data. The geographic scope of the analysis for invasive plant species is the National Forest System lands of the Nez Perce-Clearwater. This area represents the area where changes may occur to invasive species or their habitats from Forest Service management actions. For cumulative effects, the analysis area also includes the non-National Forest System lands within, and adjacent to, the administrative boundary of the Nez Perce-Clearwater. For the purposes of this analysis, the temporal scale is considered the anticipated 15-year life of the plan.

Analysis Methods, Information Sources, and Assumptions

The 2012 Planning Rule identifies invasive species as a “stressor” to natural processes. It requires the responsible official to consider stressors when developing plan components for integrated resource management in order to provide for ecosystem services and multiple uses in the plan area. The degree to which invasive plant species create stressful conditions to other natural processes is based upon a variety of factors, including weed growth characteristics, weed density, site favorability, health and stability of the native plant community, and the ability of the invasive plant to spread. Management related influences, such as removal of vegetation, active soil disturbance, and inadvertent movement of invasive plants or weed seed, are important contributors to weed introduction, establishment, and spread.

Pathways are the means and routes by which invasive species are introduced into new environments. Pathways can generally be classified as either natural or human mediated. Natural pathways are those not aided by humans and include wind and other forms of natural dispersal that can bring species to a new habitat. Human-mediated pathways are those which are created or enhanced by human activity and are intentional or unintentional. Intentional pathways are the result of a deliberate movement of a species by humans outside of its natural range, such as the introduction of biological control organisms or the movement of species for the horticultural or pet trade. Unintentional pathways are the inadvertent movement of species as a byproduct of some other human activity. For example, transferring spores or seed of invasive species by vehicles, equipment, livestock, pack stock, or recreational gear and the movement of aquatic invasive species from recreational watercraft and ballast water discharge. The term "vector" is viewed as a biological pathway for a disease or parasite, such as an organism that transmits pathogens to various hosts and is not completely synonymous with the much broader definition of a pathway.

In general, the analysis assumes removal of ground cover and increased ground disturbance corresponds with increased risk of invasive plant establishment. An increase in pathways also corresponds to a higher potential for invasive plant dispersal and spread. Roads, trails, livestock, and ground disturbance from recreation use, wildland fire, and timber harvest and fuels treatments can provide ideal pathways for the introduction of invasive species.

The analysis also assumes that the Nez Perce-Clearwater will follow all laws, regulations, and policies that relate to managing National Forest System land. The Land Management Plan is designed to supplement, not replace, direction from these sources. Other Forest Service direction, including laws, regulations, policies, executive orders, and Forest Service directives found in manuals and handbooks, are not repeated in the Land Management Plan.

Survey, inventory, and treatment data are stored in the Natural Resource Manager’s Threatened, Endangered, and Sensitive Plants and Invasive Species national database. This database is continually updated. Accomplishment reports are generated at the beginning of each fiscal year, and forest plan monitoring reports are generated every two years. Inventory records do not represent all infestations and are primarily associated with project, treatment, and early detection efforts. Treatment records represent fiscal year activity priorities. Many areas of the Nez Perce-Clearwater have not yet been inventoried for invasive species infestations, including wilderness and other remote areas. There is also a lack of information on areas that are weed free. The Natural Resources Manager database is continually updated with field observations that are reported by Forest Service personnel and contactors. It is assumed that the establishment of new undocumented invasive plant infestations has likely occurred and is not reflected in the existing condition description for invasive plant infestations.

Measurement Indicators

Risk of invasive species introduction, establishment, and spread are assessed by evaluating the difference in frequency, intensity, or type of management activity or natural processes by alternative, insofar as they may potentially remove ground cover and increase ground disturbance or pose as pathways. Table 103 outlines the indicators and measures used to compare differences between alternatives associated with invasive plant species.

Table 103. Invasive plant species measurement indicators.

Indicators	Measures
Potential soil disturbance prone to introduction by invasive plants	• Acres of ground disturbing activities, specifically timber harvest and fuels treatments and prescribed fire • Acres affected by livestock grazing, measured as a qualitative assessment of disturbance from livestock grazing and management practices.
Pathways for invasive plant spread, including recreational travel, livestock grazing, and timber harvest and fuels treatment activities	• Change in summer recreation opportunity spectrum • Risk of opportunity for recreation travel on open roads and trails that serve as a pathway for weed spread • Acres of projected timber harvest and fuels treatment • Risk of invasive plant spread from livestock grazing in transitory range

Affected Environment

Existing Condition

Invasive species are among the most immediate environmental and economic threats facing National Forest System lands, grassland, and aquatic ecosystems, endangering native species and threatening ecosystem services and natural resources (U.S. Department of Agriculture 2013a). Infestations are difficult to manage and can substantially change biological diversity by affecting the amount and distribution of native plants and animals. They can also have negative effects on forest regeneration, wildlife and livestock forage, native plants associated with tribal rights, landscape and soil productivity, fire cycles, nutrient cycling, riparian and hydrologic function, water quality, and human recreational activities (U.S. Department of Agriculture and U.S. Department of the Interior 2000).

The Nez Perce Tribe has ancestral and treaty-reserved rights to uses and resources on the Nez Perce-Clearwater. Invasive species pose a potential serious threat to the diversity, integrity, and health of native plant communities that are of tribal importance. Invasive plants can reduce the abundance and health of culturally important native plants by invading sacred landscapes, displacing native plants in traditional gathering sites, and stunting or reducing native plant growth or development (Pfeiffer and Steuter 1994).

The State of Idaho is responsible for overseeing and directing noxious weed management. The term noxious weed is a legal designation and is defined by Idaho Code (State of Idaho n.d.) as "any plant having the potential to cause injury to public health, crops, livestock, land or other property; and which is designated as noxious by the director of the department of agriculture." Management priorities, objectives, and activities on the Nez Perce-Clearwater are coordinated and collaborated through multiple partnerships, such as Cooperative Weed Management Areas, the Idaho Invasive Species Council, and the Idaho Weed Control Association. Currently, the Idaho State Department of Agriculture recognizes 54 terrestrial invasive plant species or noxious weeds within the State of Idaho (Idaho State Departement of Agriculture 2023).

Forest Service policy (specifically Executive Order 13112; Forest Service Manual 2900) and the national invasive species strategic framework (U.S. Department of Agriculture 2013a) identify prevention of the introduction and establishment of non-native plant species as an agency objective. This policy directs the Forest Service to determine the factors that favor establishment and spread of invasive plants, analyze invasive species risks in resource management projects, and design management practices that reduce these risks.

Allocation of funding seldom corresponds to the magnitude and potential threat of invasive species on the Nez Perce-Clearwater. Widely fluctuating funding levels hinder effective programs. Long-term prevention and control efforts require consistent annual commitment to be successful. The easiest and least expensive method of control is prevention. Awareness by land managers and the public is the key factor in a successful prevention program. Methods used to prevent invasive species from being introduced and spreading into new areas include closing infested areas to travel, washing vehicles and equipment upon entering an area, requiring the use of weed-free hay for pack animals, and using weed-free seed and straw mulch for revegetation. Manual, mechanical, biological, and chemical methods of treatment are generally limited to localized areas and those species on the State of Idaho noxious weed list. Infestations in some sites have been reduced by these measures. However, in spite of these control efforts, existing infestations continue to invade disturbed areas and intact plant communities. It is still common to see invasive plants along many roadsides, log landings associated with timber harvest, gravel pits, and other disturbed areas.

Presence and amount of invasive species is a key indicator for overall ecosystem health. The 2011 watershed condition framework assessment for the Nez Perce-Clearwater identified that terrestrial invasive species affected less than 10 percent of an HUC12 subwatershed in 94 of 220 subwatersheds and affected 20 to 25 percent of a subwatershed in 69 subwatersheds. However, 57 subwatersheds out of 220 were identified as having an invasive species footprint on over 25 percent of a subwatershed.

Current Invasive Plant Infestations

Invasive plant inventories for the Nez Perce-Clearwater record 80 different invasive plant species, occupying approximately 394,040 acres, or approximately 10 percent of the Nez Perce-Clearwater. Table 104 lists a few the more notable species and amount of infested acres.

A majority of recorded infestations on the Nez Perce-Clearwater are associated with past disturbances. Approximately 46 percent of the current inventoried invasive plant infestations occur within ½ mile of major transportation routes (system roads and trails). Approximately 14 percent of the inventoried infestations on the Nez Perce-Clearwater are within 50 feet of major system roads and trails.

Some landscapes are more susceptible to invasion than others due to the productivity of the sites and the similarity of environmental conditions from where the plant originated. The degree of susceptibility of a location can affect the rate of spread and the extent or size of the infestation. Invasive plant species, including those that are formally designated by states as noxious weeds, have disrupted natural processes on nearly 100 million acres in the United States and are spreading at an estimated rate of 14 percent per year (U.S. Department of Agriculture 2001a). Invasive weeds are spreading within National Forest System lands at a rate of 8 to 12 percent per year (U.S. Department of Agriculture 1998a).

Additional inventory and monitoring are needed to determine the actual rate of spread on the Nez Perce-Clearwater. Existing information suggests that the rate of spread is greater on the drier, low elevation plant communities. Cheatgrass (*Bromus tectorum*), along with other annual brome grasses, ventenata (*Ventenata dubia*), and medusa head (*Taeniatherum caput-medusae*) have become dominant in some of the low elevation bunchgrass communities.

Many roadless and wilderness areas remain relatively weed free because of healthy undisturbed native plant communities where few mechanisms exist to spread invasive species. Early detection and treatment of invasive plant species in these relatively weed free areas is a management priority.

Some invasive plants have become well-established and continue to increase in dominance within native plant communities. Expansion in some areas is out-pacing containment and control efforts. New infestations along roads and trails, both on National Forest System lands and on adjacent state and private lands, are occurring. Invasive plant species that have the ability to infest and impact large areas, listed in Table 104, are of particular concern.

Table 104. Invasive plant species common name and scientific name and infested acres on the Nez Perce-Clearwater.

Common Name	Scientific Name	Infested Acres
Spotted knapweed	*Centaurea stoebe ssp. micranthos*	160,623
Rush skeletonweed	*Chondrilla juncea*	17,900
Yellow star-thistle	*Centaurea solstitialis*	106,177
Meadow hawkweed	*Hieracium caespitosum*	19,699
Orange hawkweed	*Hieracium aurantiacum*	3,652
Common crupina	*Crupina vulgaris*	14,630
Dalmatian toadflax	*Linaria dalmatica*	1,760
Scotch thistle	*Onopordum acanthium*	6,715

Data Source: Forest Service Natural Resources Management database, accessed March 2021.

Spotted knapweed is by far the most rapidly spreading invasive species on the Nez Perce-Clearwater. This aggressive plant functions primarily as a pioneer species on disturbed sites, although it has also evolved the capability to invade already occupied sites. Knapweed's extremely aggressive character is compounded by its long-lived seed. Yellow star-thistle, like many destructive weeds, can produce several thousand seeds per plant, many of which may remain alive and dormant in the soil for several years.

Some landscapes are more susceptible to invasive species invasion than others due to the similarity of environmental conditions in the area where the invading plant originated and the productivity of the site being invaded. The dry, low-elevation grasslands and open pine timber stands of the Salmon River and Clearwater River canyons are particularly prone to invasive weed establishment. These drier habitats are often similar in climate to that of the native range of the invasive weeds. This susceptibility can affect the rate of spread and the extent or size of infestations.

The introduction of invasive weeds has highly altered grassland steppe communities within the South Fork Clearwater Subbasin. Annual grasses and other invasive weeds are well established at low elevations. Fire behavior and soil productivity may change in response to these altered plant communities (U.S. Department of Agriculture 1998b).

The occurrence of invasive species within the Salmon River Canyon, including the Frank Church-River of No Return Wilderness, is of concern to managers and wilderness users due to the potential adverse ecological effects of these invaders (U.S. Department of Agriculture 2007g). Invasive plants threaten every aspect of ecosystem health and productivity in forests and rangelands and on public and private lands (U.S. Department of Agriculture 1998b). Many invasive plants are aggressive and can invade new areas at an alarming rate because of explosive seed production and physiological adaptations to disturbed or droughty sites. Aggressive invasive species, such as purple loosestrife, yellow star-thistle, rush skeletonweed, and spotted knapweed, are capable of outcompeting native plants and altering ecosystem conditions and processes.

Invasive plants are also a growing concern in the Selway-Bitterroot Wilderness and surrounding areas. Without adequate control measures, invasive plants will continue to expand into new areas and the number of new species will increase. Invasive plants threaten wilderness values in the Selway-Bitterroot Wilderness, namely native plant communities and natural ecosystems. Invasive species are a threat to the flora and fauna associated with or dependent upon the native plant communities being displaced; in addition, physical regimes, such as those associated with fire and hydrology may be altered. These natural functions and features of the landscape are a cornerstone of wilderness values (U.S. Department of Agriculture 2009c).

Over an 8-year period (FY 2015-2022), a total of 77,616 acres of invasive plants were treated on National Forest Systems lands on the Nez Perce-Clearwater (Project record citation and footnote), averaging approximately 9,700 acres per year. Specific treatment levels vary depending on program funding levels and project priorities. Treatments are primarily chemical herbicide applications but also included manual, mechanical, and biological controls. There has been no aerial application of herbicides on the Nez Perce-Clearwater. Treatments were accomplished by Forest Service personnel, through contract specifications, and through participating agreements with county weed districts and other partners. Given the limited funding levels, the Nez Perce-Clearwater has developed a management strategy that gives priority to prevention and the early detection and rapid response tactic. Secondary priorities for treatment include areas disturbed by road maintenance or construction, wildland fire, and vegetation management and fuels treatment projects; pathway routes such as roadsides and recreation sites; and areas with specific funds designated for invasive species treatments.

Mechanisms for the spread of invasive species are road maintenance equipment, log haul trucks, all-terrain or off-highway vehicles, passenger cars and trucks, and livestock. Seeds of many species are also wind or animal dispersed (wildlife and livestock). Roads, trails, and rivers have been identified as the primary conduits or pathways for invasive plant establishment and spread (Interior Columbia Basin Ecosystem Management Project 1997). Managers face a continued threat from potential new invasive species. The use of recreational vehicles and watercraft, riding and pack stock, livestock grazing, and fire suppression activities may exacerbate the spread of potential new invasive species. The threat of aquatic invasive species has become more of a concern on the Nez Perce-Clearwater in the last decade. Although there were no detections of Dreissenid mussels in the 2020 monitoring season, there have been consistent detections of Asian clams (*Corbicula fluminea*) throughout the Snake River from the Twin Falls, Idaho area downriver to Lewiston, Idaho. The Nez Perce-Clearwater is highly susceptible to the introduction of this species. Many endemic gastropods are found in the major river systems, particularly in the Salmon River. The sheer number of endemic aquatic species within the planning area is notable and exemplary within the western United States and are highly susceptible to impacts from increases in aquatic invasive species. The spread of aquatic invasive species can occur through various pathways including discharging ballast water, moving watercraft between water bodies without removing invasive plants and animals, and releasing bait into water bodies.

Invasive species cause undesirable ecological impacts. Species arrived in this country with few or no natural pathogens or controlling agents, such as insects, increase in density and out-compete native species. Terrestrial and aquatic invasive species are capable of successfully expanding their populations into new ecosystems and can create lasting negative impacts to native plant communities. Impacts from noxious weeds can be exacerbated by fire, native pests, weather events, human actions, and environmental change (U.S. Department of Agriculture 2013a).

Disturbance is widely recognized as a primary influence on plant community composition and is frequently implicated in the spread of invasive weeds (Hobbs and Humphries 1995). Disturbance is defined as “any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment” (White and Picket 1985). Parks et al. (2005) examined the patterns of invasive plant diversity in northwest mountain ecoregions and found an overwhelming importance of disturbance in facilitating the establishment of non-native plants. Disturbances can occur as a result of natural events, such as wildfire, floods, wind events, and animal disturbances. Disturbance can also result from human activities, such as construction of roads and trails, timber harvest and fuels treatments, site preparation, prescribed fire, livestock grazing, and off-road use of all-terrain vehicles and utility vehicles. Fire suppression efforts can also result in disturbances by clearing vegetation and exposing mineral soils. Fire-line disturbances create suitable conditions for many non-native species to become established (Parks et al. 2005).

At local scales, invasive species composition and abundance are generally highest in and around disturbed patches, corridors, and edges, such as riparian corridors, transportation corridors, and fuel treatments (Benninger-Traux et al. 1992, Gelbard and Belnap 2003, Larson 2003). Buckley et al. (2003) found that features common in timber harvest areas, such as skid trails, landings, and haul roads are likely to support populations of non-native plants. Their research also suggests that haul roads, skid trails, and main forest routes serve as primary conduits for entry of introduced species into the interior of managed stands. At regional or landscape scales, composition and abundance of non-native invasive plants tend to be lower in protected or undeveloped areas than in human-dominated landscapes or landscapes fragmented by human use (Barton and Crispin 2003). Although, natural disturbance can be a major contributor to increases in invasive species abundance, most of today's invasive plant problems arise from past and present human activities (Hobbs and Humphries 1995).

It is Forest Service Policy (FSH 2109.14-53) that post-treatment evaluation be conducted for all projects involving pesticides. Treatment efficacy data transcends into the overall program performance outcome measure. The objective of the treatment effectiveness monitoring is to evaluate performance by measuring the changes in the characteristics of the infestation as a result of treatment activities. By monitoring the treatment results over time, a measure of overall programmatic treatment efficacy can be determined and an adaptive management process can be used in subsequent treatment activities.

National Invasive Species Program and Budget Guidance requires monitoring treatment effectiveness of 50 percent of acres treated each fiscal year. For example, if 1000 acres were treated in the current fiscal year then 500 acres of any treatment must be monitored for effectiveness. This is documented in the annual accomplishment report.

For the time period 2015 to 2022, the Nez Perce-Clearwater monitored approximately 74,000 acres, or 9,250 average acres annually. Treatment was successful in killing most of the target species population. The efficacy for treatments was on average 89 percent for mechanical/physical treatments and 83 percent for herbicide application treatments. Overall, 76 percent of the treated acres were restored during eight year time period. An area treated against invasive species has been 'restored' when the targeted invasive species was controlled or eradicated directly as a result of the treatment activity.

Environmental Consequences

Effects Common to All Alternatives

Management Direction under All Alternatives

Management under all alternatives would aim to slow the introductions and spread of new invaders, as well as prevent existing invasive species from establishing new non-infested areas. The Nez Perce-Clearwater would continue to manage invasive species with the most effective options in conjunction with partners. The Nez Perce-Clearwater would continue to conduct weed treatments with the most effective options as they become available and to implement mitigations, such as using the weed free forage program and enforcing vehicle and equipment washing and inspections for contract work.

Forest Service Manual 2900 – Invasive Species Management – sets National Forest System policy, responsibilities, and direction for the prevention, detection, control, and restoration of the effects from aquatic and terrestrial invasive species, including vertebrates, invertebrates, plants, and pathogens. This invasive species systems approach is also outlined in the Forest Service National Strategic Framework for Invasive Species Management (U.S. Department of Agriculture 2013a). Forests must initiate, coordinate, and sustain actions to prevent, control, and eliminate priority infestations of invasive species in aquatic and terrestrial areas of the National Forest System using an integrated pest management approach, and collaborate with stakeholders to implement cooperative invasive species management activities in accordance with law and policy. All National Forest System invasive species management activities will be conducted within the following strategic objectives:

Prevention is a proactive approach taken to manage all aquatic and terrestrial areas within the National Forest System in a manner to protect native species and ecosystems from the introduction, establishment, and spread of invasive species. Prevention can also include actions to design public-use facilities to reduce accidental spread of invasive species and actions to educate and raise awareness with internal and external audiences about the invasive species threat and respective management solutions. Prevention measures include cleaning and drying watercraft and equipment between watersheds, washing vehicles and equipment upon entering a project area, establishing weed-free staging areas for emergency and daily operations, and potentially closing infested areas to travel. In addition, the Nez Perce-Clearwater enforces the Regional Noxious Weed Order, which prohibits possessing, storing, and transporting straw, hay, grain, seed, or other forage or mulch products without documentation that it is certified as weed free by a state certification process that meets or exceeds the North American Weed Free Forage standards or similar standards. The Nez Perce-Clearwater provides education and outreach on prevention practices through the Play Clean Go, Clean Drain Dry, Don't Move Firewood, and Idaho Weed Awareness Campaigns.

Early detection and rapid response are important components of invasive species management for the Nez Perce-Clearwater and its collaborating partners. Early discovery and identification of newly arrived invasive species before they become widespread is critical to their eradication or control. Rapid response once a new invasive species is discovered is the most effective method for managing a newly arrived species. The Idaho State Department of Agriculture's annual monitoring program includes surveys and sample collection for invasive plants, snails, clams, mussels, and crayfish. The Idaho State Department of Agriculture and its partners continue to monitor Idaho waterways for various listed aquatic invasive species. To date, no evidence of Quagga mussels (*Dreissena bugensis*) or zebra mussels (*D. polymorpha*) has been found in Idaho or anywhere in the Columbia River Basin. The Nez Perce-Clearwater has been participating in a National Forest pilot program using mobile applications to involve the public in early detection of high priority invasive species.

Control and Management to actively reduce or eliminate invasive weed populations is required for an integrated pest management approach. This may include manual, mechanical, biological, and chemical ground-based herbicide applications. All treatment measures used on the Nez Perce-Clearwater have been reviewed and approved through site specific National Environmental Policy Act analysis. Invasive weed infestations have been reduced significantly by these integrated weed management techniques. However, despite these coordinated weed management efforts, invasive species infestations and the threat of introduction persists on the Nez Perce-Clearwater. In addition, climate studies indicate there may be generally warmer and drier conditions across the region. If this change occurs, there is a risk of higher severity wildfires, which may result in increased bare soil following a wildfire event. The combination of warmer and drier climate and higher severity wildfires may favor the proliferation of invasive weeds. The amount of weed infested acres to be treated each year by various methods is largely dependent upon annual funding availability.

Restoration is a strategy to pro-actively manage aquatic and terrestrial areas within the National Forest System to increase the ability of those areas to be self-sustaining, resistant, and resilient to the establishment of invasive species. Seeding temporary or closed roads to reduce the potential for introduction and expansion of invasive species infestations is an example of this strategy and has been occurring on the Nez Perce-Clearwater for many years. Desirable non-native mixes of grasses and forbs have been used in the past, but native grasses and forbs have been used more frequently in recent years.

Organizational Collaboration with other agencies, researchers, landowners, and interested groups increases the management effectiveness against invasive species infestations impacting or threatening Nez Perce-Clearwater resources. Cooperative weed management areas are organizations that coordinate noxious weed management goals and resources across jurisdictional boundaries. Cooperative weed management areas provide the mechanism that allows federal, state and local agencies, along with other stakeholders and landowners to set common objectives and priorities for the prevention and management of invasive weeds. The Nez Perce-Clearwater participates in five cooperative weed management areas – Palouse, Clearwater Basin, Upper Clearwater, Frank Church, and Salmon River. The Nez Perce-Clearwater also coordinates with the Idaho State Department of Agriculture in several of the agency's invasive species programs, such as the statewide aquatic invasive species management and control program focused on protecting the integrity of the state's water bodies from the biological degradation caused by aquatic plants and pests. Additionally, the Nez Perce-Clearwater works with the Nez Perce Tribe Bio-Control Center, which specializes in rearing and providing insect "agents" to help control or manage targeted invasive plants.

Invasive species management activities on the Nez Perce-Clearwater are guided by conditions and constraints of specific Environmental Impact Statements or Environmental Assessments for management and treatment, including:

- Nez Perce National Forest Noxious Weed Control Program Environmental Assessment (U.S. Department of Agriculture 1988c)
- Nez Perce National Forest Noxious Weed Treatment Biological Opinion (U.S. Department of Commerce 2009)
- Frank Church-River of No Return Wilderness Noxious Weed Treatments Final Supplemental Environmental Impact Statement (U.S. Department of Agriculture 2007g)
- Selway-Bitterroot Wilderness Invasive Plants Management Project Final Environmental Impact Statement (U.S. Department of Agriculture 2009c)
- North Fork Clearwater Ranger District Noxious Weed Treatment Environmental Assessment (U.S. Department of Agriculture 2005)
- Palouse Ranger District Noxious Weed Control Environmental Assessment (U.S. Department of Agriculture 2000b)
- Lochsa and Powell Ranger Districts Invasive Weeds Environmental Assessment (U.S. Department of Agriculture 2007b)
- Gospel-Hump Wilderness Invasive Plant Management Environmental Assessment (U.S. Department of Agriculture 2017a)

Per Forest Service policy found in Forest Service Manual 2900, it is required to determine the risk of introducing, establishing, or spreading invasive species associated with any proposed action as an integral component of project planning and analysis and, where necessary, provide for alternatives or mitigation measures to reduce or eliminate that risk prior to project approval.

Effects Common to All Alternatives

Invasive plant species would continue to have a presence on the Nez Perce-Clearwater landscape under all alternatives. Some species may contract in density as new treatment and biological options become available, while other weeds would expand in range and density. Some invasive species have become almost “naturalized” to vegetation communities on the Nez Perce-Clearwater, and some level of their presence would persist under all alternatives. Other invasive species have become well-established and continue to increase in dominance within native plant communities.

Invasive species have substantially increased across the Nez Perce-Clearwater over the last several decades, with a present infestation level of approximately 394,040 acres. Assuming the national average annual rate of spread of 8 to 12 percent per year (U.S. Department of Agriculture 1998a) applies, the Nez Perce-Clearwater could expect to encounter an increase in invasive plant infestations of approximately 31,000 to 47,000 acres per year.

Climate Change

Climate change is likely to result in differing responses among invasive plant species due to differences in their ecological and life history characteristics. As reported in the Northern Rockies Adaptation Partnership Vulnerability Assessment (Halofsky, Peterson, et al. 2018a), climate change could result in either range expansion or contraction of an invasive weed. For example, modeling indicates that leafy spurge may contract, and spotted knapweed may shift in range. Invasive weeds are generally adaptable, capable of relatively rapid genetic change, and many have life history strategies which can enhance their ability to invade new areas in response to changes in ecosystem conditions. Warmer temperatures and associated drier conditions, more severe or frequent droughts, and more favorable conditions for wildfire may increase the ability of invasive plants to establish and out-compete native plants. These changes may provide more opportunities for invasive weeds to gain an advantage over native species and spread within and beyond the project area boundaries. This potential effect is common to all alternatives.

The success of invasive plants in native plant communities is highly influenced by a variety of factors including temperature, precipitation, soil disturbance, and plant density (Pauchard et al. 2009, Poorter and Navas 2003, Eschtruth and Battles 2009). Temperature shifts can alter invasive weed dynamics. The greatest effect to plant communities from climate change rises from shifts in maximum and minimum temperatures rather than from change in annual mean temperatures (Stachowicz et al. 2002). These changes can give invasive species an early season start, resulting in increased growth and recruitment relative to native species (Traill et al. 2010).

The effects of climate change on invasive weed distributions are likely to be complex (Crimmins et al. 2011). Some studies predict a shift in the range of some invasive weed species to higher latitudes or higher elevations (Chen et al. 2011). Pauchard et al. (2009) suggest that the threat posed to high-elevation biodiversity by invasive plant species is likely to increase because of globalization and climate change. Other studies, such as Harsch and Lambers (2015), suggest that distribution shifts in response to recent climate change could occur in either an upward or downward direction.

Changing climate may affect other natural processes, which in turn may influence invasive weed populations and potential spread. Climate change may influence the effects of wildfire in a variety of ways, including increased fire intensity. Increased fire intensity may result in an increase in bare soil vulnerable to the establishment of invasive plant species. Other disturbances or shifts in historical patterns may be affected by climate change and, in turn, affect the spread of invasive species. As the agency responds to climate change by new, different, or more land and vegetation management actions, those disturbances could provide suitable conditions for invasive plants.

Increased Public Use and Mobility

Public uses on National Forest System lands are expected to grow substantially over the next several decades (Cordell 2012). Pressures on undeveloped, natural land for recreation purposes due to growth in the United States' population will be moderate to high throughout most of the west (Bosworth 2004). The potential for invasive species being introduced and spread by recreation and motorized travel is also expected to increase.

In addition, rapidly increasing global transportation is facilitating the distribution of exotic species among continents well beyond their native range (U.S. Department of Agriculture 2013a). Anderson et al. (2015) found that tourism is indeed a pathway for spread of non-native species across the globe. Since most invasive species in the United States originated in other countries, it is imperative that ways to minimize the global spread of invasive species are explored (Federal Interagency Committee for the Management of Noxious and Exotic Weeds 2003). As recreational uses of the forests increase and visitors come from distant locations, the risk of new invasive species being introduced to the forest is high. Since managers may not be familiar with identifying new species, new invasive species may go undetected for long periods. Once established, invasive species frequently have long lag times before they begin to exhibit dramatic effects. Introduced species that initially escaped many decades ago are only now being recognized as invasive (Federal Interagency Committee for the Management of Noxious and Exotic Weeds 2003).

Globalization is likely to increase within Idaho as the population of the state continues to grow. Globalization is defined as the free movement of goods, capital, services, people, technology, and information. It facilitates and intensifies the spread of invasive weed species (Meyerson and Mooney 2007). As a result, the extent and density of invasive plant infestations, as well as the number of invasive plant species, has the potential to increase on National Forest System lands within the plan area as commodity and recreational uses increase with a growing population.

Effects to No Action Alternative

Management Direction Under the Current Forest Plans

The 1987 Nez Perce and Clearwater Forest Plans, as amended, are the existing management direction being used by the Nez Perce-Clearwater to address non-native invasive plant species. This direction represents the No Action Alternative and is the baseline to which the action alternatives are compared.

The 1987 Forest Plan for the Nez Perce National Forest (U.S. Department of Agriculture 1987b) includes a forestwide objective under the Range section to emphasize noxious weed control. A forestwide standard under the Range section outlined the following weed control direction:

- Implement a weed control program to confine present infestations and prevent establishment of new areas of noxious weeds;
- The national forest will favor biological control for noxious weeds that have effective host insects;
- Where biological control is not effective, a combination of hand grubbing and spot application of herbicides will be used;
- This program will be coordinated with county, state, and other federal agencies; and

- All National Environmental Policy Act requirements will be completed prior to using any herbicide.

Additional Nez Perce National Forest Plan direction requires coordination with Idaho County on rights-of-way, road maintenance, law enforcement, noxious weed control, and other activities to produce mutual benefits. Management areas specific standards for range management include treating noxious weed infestations that threaten adjacent lands and emphasizing biological methods to control noxious weeds in allotments within the Rapid River Wild and Scenic River. The plan also outlined a projected noxious weed control output of 250 acres per year in the Range section.

The 1987 Forest Plan for the Clearwater National Forest (U.S. Department of Agriculture 1987a) includes a forestwide objective under the Range section to inventory, map, and complete an activity schedule for significant noxious weeds during the first planning period (10 years), with the focus on livestock grazing allotments. A forestwide standard specified that noxious weeds were to be controlled on a case-by-case basis if their presence conflicted with the range resource or become detrimental to other resources and uses. The plan also projected noxious weed treatment on 380 acres annually, with 300 acres occurring within range allotments and 80 acres along the recreational portion of the Middle Fork Clearwater Wild and Scenic River corridor.

The Clearwater National Forest Plan also identified the research needs to determine the autecology of specific noxious weeds and develop and evaluate probable biological control methods of those weeds. A noxious weed situation report was included as Appendix N in the Forest Plan and outlined existing condition and management guidance.

In 1995, the Chief of the Forest Service amended the Nez Perce and Clearwater Forest Plans to implement an interim strategy for managing anadromous fish-producing watersheds on National Forest System lands. The amendment included management direction for riparian areas (RA-3) to apply herbicides, pesticides, and other toxicants and other chemicals in a manner that does not retard or prevent attainment of Riparian Management Objectives and avoids adverse effects on listed anadromous fish.

Effects of the No Action Alternative

At the time the 1987 forest plans were developed, the extent and magnitude of ecological issues that invasive species would create for the Nez Perce-Clearwater were unforeseeable. The direction in the 1987 forest plans is very limited and primarily focuses on the control of noxious weeds. While an Integrated Weed Management approach exists as national Forest Service direction, it is not addressed in the current forest plans. Brief general statements about cooperating with other agencies and landowners are provided. Direction to improve the level of cooperation with adjacent landowners and sustain cooperative weed management programs is not provided. Under the No Action Alternative, the targeted amount of invasive species treatment acres is very low and focused primarily on livestock grazing allotments.

Despite the lack of specificity for invasive species management direction in the 1987 forest plans, they encompass current practices and are considered appropriate to address invasive plant species while being flexible to budget constraints. Prioritizing treatment areas and control strategies have been effective only to the extent that funding and resources have been available to implement them. There is still a trend of increasing weed introduction and spread given limited resources for prevention and treatment. Neither of the current plans contain direction related to aquatic invasive species.

Decisions for individual invasive weed environmental assessments and environmental impact statements provide more current guidance for invasive weed management on the Nez Perce-Clearwater and would continue to be available to treat infestations. These decisions included adaptive management strategies to determine where, when, and how to treat sites, considering such factors as weed species, treatment prioritization, and ecological importance of the site.

Effects Common to Action Alternatives

To develop a land management plan consistent with maintaining ecological sustainability, the plan must include plan components, including standards or guidelines, designed to maintain, restore, or promote the ecological integrity of terrestrial, riparian, and aquatic ecosystems; maintain the diversity of plant and animal communities; and support the persistence of native species within the plan area. (FSH 1909.12, Chapter 20, Section 23.1). To maintain or improve ecological integrity at the landscape scale, land management plans should include plan components that provide for opportunities for partnerships to support restoring ecological conditions at the appropriate geographic scale (FSH 1909.12, Chapter 20, Section 23.11b (5)(a)(6).

The Nez Perce-Clearwater Land Management Plan includes the following goals to emphasize the Nez Perce-Clearwater's intent to continue working with partners using an all lands approach to invasive species management:

- FW-GL-INV-01. The Nez Perce-Clearwater actively participates in Cooperative Weed Management Areas, which are used to determine weed treatment priorities, projects, budgets, and annual programs. Public awareness is promoted using various forms of outreach through the Cooperative Weed Management Areas.
- FW-GL-INV-02. The Nez Perce-Clearwater works with federal, state, and county agencies, tribes, non-government organizations, permittees, and adjacent landowners to support integrated pest management, including invasive species prevention, early detection, and rapid response, control and containment, restoration and rehabilitation, and inventory and monitoring activities.

Diversity of Ecosystems

As directed by the 2012 Planning Rule, land management plans must include plan components, including standards or guidelines, to maintain or restore the diversity of ecosystems and habitat types throughout the plan area. In doing so, the plan must include plan components to maintain or restore key characteristics associated with terrestrial and aquatic ecosystem types and rare aquatic and terrestrial plant and animal communities (36 CFR 219.9(a)(2)). To develop the Land Management Plan consistent with maintaining ecosystem diversity, the plan must include plan components, including standards or guidelines, designed to maintain, restore, or promote ecosystem diversity and habitat types. The diversity of terrestrial, riparian, and aquatic ecosystems and habitats is fundamental to providing ecological conditions that support the abundance, distribution, and long-term persistence of native species and diversity of plant and animal communities.

Invasive species pose a potential serious threat to the diversity, integrity, and health of native plant communities. The Nez Perce-Clearwater contains a mosaic of forest, grassland, meadows and shrubland vegetation. The Land Management Plan includes six desired conditions that promote meadows, grasslands, and shrublands health and support native plant communities within the planning area (FW-DC-GS-01 to 06). The desired conditions also emphasize invasive plant species either are not present or occur with low cover.

The Land Management Plan recognizes the importance of invasive species management by including a desired condition specific to invasive species (FW-DC-INV-01). It guides future forest management to trend towards a forest condition where invasive species either are not present or occur at low levels to allow watersheds, vegetation communities, and aquatic ecosystems to retain their inherent resilience and resistance to respond and adjust to disturbances. Plant communities retain their historic diversity and provision of values to fauna. Objective FW-OBJ-INV-01 describes the intent for treating 6,000 acres annually to contain or reduce non-native invasive plant density, infestation area, or occurrence, with emphasis given to new invader species. This is a substantial increase in treatment area compared to the existing 1987 forest plans that proposed 250 and 380 acres per decade, primarily in range allotments, and is more aligned with the current treatment acres. Treatments may include manual, mechanical, biological, and chemical ground-based herbicide applications. Treatments will primarily occur in Management Area 3 where 50 percent of the known invasive species infestations occur.

Soil Disturbance

Based on Forest Inventory and Analysis surveys, there is an estimated 3 percent bare ground in forested areas and an estimated 14 percent in non-forested areas. Ground cover and soil disturbance can exacerbate the spread and establishment of invasive plant species. Ground disturbing activities, such as timber harvest, fuels treatments, prescribed burning, road construction and reconstruction, and uncharacteristic wildfire events have created favorable conditions for invasive plant establishment by clearing vegetation and exposing mineral soils. Recreational activities also have the potential to cause ground disturbance, especially around trailheads, trails, campgrounds, and other developed and dispersed recreation sites.

To reduce the probability of establishment or expansion of invasive weeds, the Land Management Plan includes guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds. Guideline FW-GDL-SOIL-02 specifies that project activities should provide sufficient effective ground cover, such as litter, fine, and coarse wood material, or vegetation with a post-implementation target of 85 percent aerial extent of an activity area to retain soil moisture, support soil development, provide nutrients, and reduce soil erosion. The depth and distribution of organic matter should reflect the amounts that occur for the local ecological type and natural wildland fire regime. The Land Management Plan also includes a guideline to address invasive weed management as part of post-fire habitat restoration (FW-GDL-INV-03).

Livestock grazing can create soil disturbance that enhances germination and establishment of invasive species. There are approximately 612,766 acres of active grazing allotments on the Nez Perce-Clearwater. Localized areas where congregation occur, such as supplement locations, fence lines, and watering sites and water developments can contribute to reduced ground cover and can become potentially susceptible to invasive plant establishment. To allow forage plants to maintain vigor, root development, and soil cover, guideline FW-GDL-GRZ-03 specifies that general upland forage utilization should not exceed 35 to 55 percent. Proposed guideline FW-GDL-ARGRZ-01 establishes minimum end of season stubble heights of 10 to 15 centimeters (four to six inches) along the greenline for low gradient streams.

Pathways for Invasive Specie Spread

Land management plans should consider stressors, such as invasive species when developing integrated plan components (36 CFR 219.8 (a)(1)(iv)). A stressor is a factor that may directly or indirectly degrade or impair ecosystem composition, structure, or ecological process in a manner that may impair its ecological integrity. The presence and distribution of non-desirable invasive species affects composition, and the rate of invasion by invasive species affects function and ecological processes. If the rate is too quick, the ecosystem can lose the ability to adapt to changes imposed by the stressor.

Domestic livestock have the potential to transport and spread invasive weed seed. Guideline FW-GDL-INV-01, specifies that permittees would be required to implement invasive plant prevention measures associated with livestock grazing. Management approaches recommended in Appendix 4 of the Land

Management Plan may include confining livestock to a weed free pasture before entering allotments on National Forest System lands, cleaning permittee-owned equipment used in managing livestock, and feeding saddle horses used for allotment management weed free hay before entering National Forest System lands.

The threat of aquatic invasive species has become more of a concern on the Nez Perce-Clearwater in the last decade. The spread of aquatic invasive species can occur through various pathways including discharging ballast water, moving watercraft between water bodies without removing invasive plants and animals, and releasing bait into water bodies. To highlight the intent to continue working with partners and to address aquatic invasive species, the Nez Perce-Clearwater Land Management Plan includes goal FW-GL-WTR-01, emphasizing that the Nez Perce-Clearwater works with appropriate agencies to control the expansion of aquatic invasive species. The current 1987 forest plans do not contain specific standards or guidelines related to aquatic invasive species. Under the Action Alternatives, proposed desired condition FW-DC-INV-01 seeks to limit the establishment of invasive species to aquatic ecosystems. To move towards this desired condition, prevention measures for aquatic species should be designed and implemented at the project level. These activities could include, but are not limited to, proactive measures to avoid accidental introduction, transporting water across drainage boundaries for fire suppression, constructing stream fords, operating equipment in a riparian area and near a water course, and the use of pumps and sumps for fire suppression, or construction related dewatering activities. To prevent the spread of invasive species**,** standard FW-STD-WTR-05 requires that **w**hen drafting water, pumps, charged hoses, and drafted water shall not be backflushed or discharged into stream channels, wetlands, or other water bodies.

Wildfire suppression vehicles and equipment used during fire suppression activities can act as pathways for invasive species spread. To prevent the introduction of non-native species, guideline FW-GDL-INV-02 stipulates equipment operated by Forest Service employees and agency-authorized personnel that comes in contact with a water body should be inspected and cleaned for aquatic invasive species prior to use in a water body or when moving between subbasins (HUC08) during non-emergency operation, including pumps used to draft water from water bodies, water tenders, and helicopter buckets. Additionally, the National Invasive Species Council and Wildland Fire Leadership Council Memorandum (U.S. Department of the Interior 2022a) outlined direction for multiple federal agencies to provide support and resources to the integration and coordination of wildland fire and invasive species management efforts. Also, Forest Service direction requires all fire suppression activities to follow protocols outlined in the Guide to Preventing Aquatic Invasive Species Transport by Wildland Fire Operations (National Wildfire Coordinating Group 2017a), the Northern Rockies Coordinating Group Supplemental (Northern Rockies Coordination Group 2018b), and the Northern Rockies Coordinating Group Directive on Aquatic Invasive Species Protocols (Northern Rockies Coordination Group 2018a). Fire operations would also follow industry standards for invasive species decontamination, such as vehicle washing.

The Management approaches outlined in Appendix 4 of the Land Management Plan provide more information on organizational collaboration and invasive species management strategies, including invasive species prevention, early detection and rapid response, control and containment, restoration and rehabilitation, and inventory and monitoring activities.

As outlined in Appendix 3, monitoring includes the evaluation of trends in invasive species infestation number, size, and density; the effect of invasive species infestations on native vegetation and other resources the effect of treatments on target weeds; the effect of treatments on desirable vegetation; and effectiveness of treatments as implemented. Long-term monitoring of invasive species abundance and distribution provides information on infestation dynamics. By monitoring treatment results over time, a measure of overall programmatic treatment efficacy can be determined, and an adaptive management process can be used in subsequent treatment activities.

Effects that Vary by Action Alternative

As directed by the 2012 Planning Rule, land management plans must contain plan components, including standards or guidelines, that maintain or restore the composition, structure, ecological processes, and connectivity of plan area ecosystems in a manner that promotes their ecological integrity (36 CFR 219.8(a) and 219.9(a)(1)), taking into account stressors, such as invasive species (36 CFR 219.8 (a)(1)(iv)). Land management plans should also include plan components designed to limit the ability of stressors to impact ecosystem integrity, such as mitigating stressors associated with forest and rangeland management. Examples include equipment impacts on soils and water or movement of invasive species via vehicles and foot travel (FSH 1909.12, Chapter 20, Section 23.11b (4)(b)(2)). The effects of management activities on the potential for invasive plant establishment and spread under the various alternatives can be categorized in two ways: a) the potential for soil disturbance, and b) the potential increase of pathways for invasive species dispersal.

Soil Disturbance

Action Alternatives vary in the number of planned activities that have the potential to cause project level soil disturbance that can exacerbate the spread and establishment of invasive plant species. Future activities which may result in soil disturbance on a relatively large scale within the Nez Perce-Clearwater include timber harvest and fuels treatments, wildfire suppression activities, prescribed fire, and new road construction. Activities resulting in soil disturbance which are in the vicinity of established invasive weed populations are particularly prone to weed invasion.

Timber harvest and fuels treatment activities, including site preparation actions, often result in some level soil disturbance during project implementation. Soil disturbance primarily occurs at landings, skid trails, and temporary roads. In addition, road construction and reconstruction needed to facilitate timber harvest activities also cause soil disturbance. Standards, guidelines, contract specifications, and project design measures would be implemented to minimize the amount of soil disturbance following these activities, but some amount of soil disturbance and bare soil is unavoidable. The direct correlation between timber harvest and fuels treatment objectives and associated soil disturbance and potential for invasive species to establish in those areas was used to differentiate effects between alternatives.

Prescribed fire also has the potential to cause soil disturbance by removing ground cover and forest floor. Depending on fire severity, prescribed fires can cause changes in biological, chemical, or physical properties. High severity burn areas have been shown to be more prone to invasion by weeds than lower severity burns.

Table 105 provides a comparison of projected soil disturbance due to timber harvest and fuels treatment activities and projected prescribed fire by alternative. Alternatives W and X have the highest potential for soil disturbance from vegetation management activities. Alternative Y and the Preferred Alternative have a higher probability of increasing soil disturbance compared to the No Action Alternative. Alternative Z is comparable to the No Action Alternative for ground disturbance potential.

Table 105. Projected soil disturbance acres from vegetation management activities by alternative.

Acres	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Timber harvest and fuels treatment average annual acres	4,300	12,600	14,000	7,500	3,700	8,825–10,000
Prescribed fire average annual acres	5,560	7,345	8,330	8,020	6,450	6,800

Even though the amount of ground disturbance varies by alternative, all Action Alternatives include guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds. Additionally, to prevent expansion of invasive plant species, guideline FW-GDL-FIRE-02 requires planned ignitions in areas highly susceptible to weed invasion to be planned and implemented with design features to address the spread of invasive species.

Pathways for Invasive Species Spread

Alternatives vary in the projected number of activities that could result in added mechanisms for invasive plant spread, including use of equipment and truck traffic associated with timber harvest and fuels treatment activities and recreational vehicular travel. Motorized travel and use across the Nez Perce-Clearwater are determined by travel plan direction and site-specific project analysis and, therefore, do not vary across alternatives. However, land allocations that find motorized travel unsuitable, such as recommended wilderness, do vary across alternatives. Changes in recreation opportunity spectrum classifications for motorized and non-motorized suitability could lead to shifts in the risk that motorized travel poses to invasive species spread. Table 106 displays the percentage of the Nez Perce-Clearwater in non-motorized and motorized summer recreation opportunity spectrum category.

Table 106. Percentage of plan area in summer recreation opportunity spectrum (ROS) categories by alternative and potential risk of invasive species spread from recreational travel.

Plan Area	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Percentage of Forest in Non-Motorized ROS Category	55	53	42	56	57	45
Percentage of Forest in Motorized ROS Category	45	47	58	44	43	55
Risk of invasive species spread from recreational travel[1]	Baseline	Higher	Highest	Lesser	Lesser	Higher

[1]Depicts the risk of opportunity for recreation travel on open roads and trails to serve as a pathway for weed spread.

Recreational vehicular travel would continue to be a pathway for invasive species spread along open roads and trails. As noted in Table 106, Alternatives W and X and the Preferred Alternative propose a higher percentage of the Nez Perce-Clearwater in the motorized summer recreation opportunity spectrum category compared to the No Action Alternative. As a result of more land allocation where motorized travel is suitable, these alternatives pose a greater risk of invasive plant spread. Alternatives Y and Z propose a lesser percentage compared to the No Action Alternative.

The transport of harvest equipment onto the Nez Perce-Clearwater, the use of that equipment during harvest activities, and log haul truck traffic have contributed to the introduction and spread of invasive plant seed. Contract specifications help prevent introduction of invasive species to units from outside or within the National Forest System lands by requiring cleaning of equipment. Other best management practices to prevent establishment of infestations include pre- and post-implementation invasive species, treatment of haul routes, and dispersing native plant seed on disturbed areas after implementation. As noted in

Table 105, the No Action Alternative and Alternatives Y and Z propose the least amount of vegetation treatment activity acres but could contribute a moderate amount of pathways for weed transport associated with timber harvest and fuels treatment activities. The Preferred Alternative has a higher timber harvest and fuels treatment objective, therefore has a higher potential for invasive species spread. Alternatives X and W would have the highest potential for invasive species spread associated with timber harvest and fuels treatment and a greater risk associated with equipment and log haul trucks transporting weed seed.

Vegetation management, such as timber harvest, prescribed fire, and wildfire that occurs in allotments can provide transitory forage that would be available for livestock grazing. As more transitory forage becomes available, livestock have the tendency to distribute themselves throughout the allotment, potentially spreading invasive plant seed into previously weed free areas. Since the potential risk of this impact occurring correlates to the amount of transitory forage area produced, the level of risk for invasive species spread is the same as outlined above for vegetation management activities.

Cumulative Effects

Invasive species spread without regard to administrative boundaries. As such, the cumulative effects of Nez Perce-Clearwater invasive species management under any alternative, including the No Action Alternative, may negatively or beneficially impact adjacent federal, state, and private lands depending upon the specific site treatment or lack thereof. Invasive species management and site-specific conditions on adjacent lands also have the potential to influence the rate and extent of introduction and spread of invasive species to Nez Perce-Clearwater lands. Under all alternatives, coordination with state and local agencies and communication with the public would continue to combat the spread of undesirable non-native invasive species.

Portions of the Nez Perce-Clearwater adjoin other national forests, each having its own forest plan (or land management plan). The Nez Perce-Clearwater is also intermixed with lands of other ownerships, including other federal, state, and private lands. Some of these entities implement their own resource management plans or are tiering to specific county resource management plans. Management plans from other federal, state, county agencies are summarized in Table 107. Actions, strategies, and prioritization of treatments under these management plans, in conjunction with the Nez Perce-Clearwater Land Management Plan, cumulatively affect the introduction and expansion of invasive species at the landscape scale.

Table 107. Summary of cumulative effects to invasive species from other resource management plans.

Resource Plan	Description and Summary of Effects
Adjacent National Forest Land Management Plans (U.S. Department of Agriculture 2010d, 1987d, 2015c)	Land management plans for National Forest System lands adjacent to the Nez Perce-Clearwater include the Payette, Wallowa-Whitman, Bitterroot, Lolo, and Idaho Panhandle National Forests. All plans address invasive species management and are consistent across all national forests due to law, regulation, and policy, and plan components are relatively consistent and compatible with overall direction.
Bureau of Land Management Cottonwood Resource Management Plan (U.S. Department of the Interior 2009)	Bureau of Land Management lands near the Nez Perce-Clearwater are managed by the Cottonwood field office. The Cottonwood Resource Management Plan contains components related to invasive species and would be complementary to the plan components proposed in the revised Land Management Plan.

Resource Plan	Description and Summary of Effects
Nez Perce Tribe Integrated Resource Management Plan (Tribe 2023)	The protection and restoration of native vegetation communities and control of noxious, invasive, or otherwise deleterious non-native plant species are high priorities. This Plan includes desired conditions that would be complementary to the plan components proposed in the revised Land Management Plan.
The Idaho Forest Action Plan Resource Assessment and Resource Strategy (Idaho Department of Lands 2020)	Identifies invasive plants as a threat and emphasizes collaboration with partners. This plan is complementary to the revised Land Management Plan related to management of invasive species.
Idaho Invasive Species Strategic Plan 2022-2026 (Idaho State Department of Agriculture 2021)	The plan sets three goals to 1) prevent the introduction of new invasive species to Idaho, 2) limit the spread of existing invasive species in Idaho, and 3) abate ecological and economic impacts that result from invasive species populations in Idaho. This plan is complementary to the Nez Perce-Clearwater Land Management Plan.
Idaho State Wildlife Action Plan (Idaho Department of Fish and Game 2017b)	This plan describes a variety of vegetation and aquatic conditions and threats related to habitat for specific wildlife species. This plan would likely result in the preservation of these habitats on state lands, specifically within wildlife management areas. This plan is complementary to the revised Land Management Plan related to management of invasive plant and aquatic species.
Soil and Water Conservation Districts Programs	The Districts are committed participants in Cooperative Weed Management. Areas Districts have active programs to prevent introductions of new invasive species, prevent the spread of invasive species, and reduce the impacts caused by invasive species.
County Resource Management Plans	County plans generally aim to maintain native vegetation communities and reduce noxious weeds. For example, goals for invasive weed management within Idaho County are 1) prevent invasion, 2) limit existing invasions, and 3) abate ecological and economic impacts.

There are several regional and statewide organizations involved in the management of noxious weeds and invasive species across Idaho. Organizations such as Idaho Noxious Weed Control Association (INWCA), Idaho Association of Noxious Weed Control Superintendents (IANWCS), Idaho State Noxious Weed Advisory Board, Idaho Invasive Species Council (IISC), the Columbia River Basin (CRB) Aquatic Invasive Species team, Western Weed Coordinating Committee (WWCC), Western Regional Panel (WRP) on Nuisance Species, Pacific Northwest Economic Region (PNWER), and Western Governors' Association (WGA) all work together to provide cohesive invasive species management.

Cooperative Weed Management Areas (CWMA) form the basic local unit for cooperation in invasive weed management actions in the State of Idaho. CWMAs are organizations that integrate noxious weed management goals and resources across jurisdictional boundaries. CWMAs provide the mechanism that allows federal, state and local agencies, along with other stakeholders and landowners to set common goals and priorities for the prevention and management of invasive weeds. Portions of the Nez Perce-Clearwater occur within the Palouse, Clearwater Basin, Upper Clearwater, Frank Church, and Salmon River CWMAs.

The Nez Perce-Clearwater also coordinates with the Idaho State Department of Agriculture in several of the agency's invasive species programs, such as the statewide aquatic invasive species management and control program focused on protecting the integrity of the state's water bodies from the biological degradation caused by aquatic plants and pests. Additionally, the Nez Perce-Clearwater works with the Nez Perce Tribe Bio-Control Center, which specializes in rearing and providing insect "agents" to help control or manage targeted invasive plants. Most counties within the plan area have agreements with the Nez Perce-Clearwater that coordinate noxious weed treatments, as well as provide a mechanism for which the Nez Perce-Clearwater can financially fund county weed control efforts on National Forest System lands.

Effects to Invasive Species from Management of Other Resources

Timber Harvest and Fuels Treatment Management

Healthy, resilient landscapes have a greater capacity to survive natural disturbances and large-scale threats to ecological sustainability, especially under changing and uncertain future environmental conditions, such as those driven by changing climate and increasing human uses (as found in Forest Service Manual 2020).

Vegetation management activities are proposed under the Action Alternatives to move current forest conditions to a more healthy, resilient landscape as described in the Forestlands desired conditions. Timber harvest and fuels treatments are most likely to occur on lands identified as suitable for timber production. All alternatives have varying amounts of land suitable for timber production and varying amounts of proposed timber harvest that have the potential to cause soil disturbance and act as a pathway for spread of invasive species.

Slash treatments, such as burning, yarding, or crushing unmerchantable material, is necessary for timber harvest to be an effective fuel treatment in ecosystems with mixed-severity fire regimes, but as noted by Martinson et al. (2008), adding surface disturbance to canopy removal might result in even greater potential for invasion by non-native plants. Slash pile burning associated with timber harvest and fuels treatments is prone to invasion by non-native species because of the intense soil heating on a small scale (Korb et al. 2004).

Most of the non-native species found following harvest and fuel treatments in Ponderosa pine forests, such as common mullein (*Verbascum thapsus*), lambsquarters (*Chenopodium album*), and prickly lettuce (*Lactuca serriola*), are not considered a threat to native plant communities (Zouhar et al. 2008). Martinson et al. (2008) referenced a study which observed increases in many non-native species following harvest and fuel treatments may not be problematic in the long-term since the species are usually transient members of recently disturbed communities.

Disturbance to ground cover and soil can exacerbate the spread and establishment of invasive plant species. To reduce the probability of establishment or expansion of invasive weeds, the Land Management Plan includes guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds.

Contract specifications help prevent introduction of invasive species to units from outside or within the National Forest System lands by requiring cleaning of equipment. Other best management practices to prevent establishment of infestations include pre- and post-implementation invasive species treatment of haul routes and dispersing native plant seed on disturbed areas after implementation.

Wildland Fire Management

Fire has long played a role in shaping the vegetation of the Nez Perce-Clearwater. The resiliency of much of the forest is dependent upon fire as a frequent disturbance process. Fire, although it is a natural and desired ecological process, can have a detrimental impact to the ecosystem post-fire, depending on the occurrence of invasive species infestations pre-fire. Fire can result in an increase in non-native species diversity and cover, whether it is a prescribed burn or a wildfire (Zouhar et al. 2008).

Wildfires would occur in the future under all alternatives, although uncertainty exists as to extent and location. Weather and climatic factors along with fuels conditions would affect intensity and spread of a fire event. Effects of wildfire on invasive species spread potential is the same across alternatives.

All alternatives project a varying among of prescribed fire. There is potential for establishment and spread of invasive plant species within burned areas, depending largely upon site-specific conditions, such as fire location, vegetation types that were burned, presence of weed infestations pre-fire, potential pathways, and fire characteristics. Disturbance to ground cover and soil can exacerbate the spread and establishment of invasive plant species. To reduce the probability of establishment or expansion of invasive weeds, the Land Management Plan includes guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds. Additionally, to prevent expansion of invasive plant species, guideline FW-GDL-FIRE-02 requires that planned ignitions in areas highly susceptible to weed invasion should be planned and implemented with design features to address the spread of invasive species, including the implementation of national and regional guidelines to prevent invasive species transport on wildland fire mobile equipment.

Wildfire suppression efforts can also create soil disturbance, increasing the potential for establishment of invasive plant species. Wildfire suppression efforts often involve constructing control lines and requiring staging areas for fire equipment and fire camps. Large influxes of firefighters and equipment from out of the immediate area can transport undesirable seed. Control lines are usually dug down to bare mineral soil and can provide sites that are very vulnerable to weed establishment and spread. While there are many weed prevention and control measures that are required by Forest Service policy (as found in Forest Service Manual 2081) that are associated with the management of wildfires and prescribe fires, there is an increased risk of weed invasions and introductions in burned areas. Since it is nearly impossible to predict the extent and location of future wildfires, quantifying the extent of soil disturbance or invasive species spread is problematic.

Wildfire suppression vehicles and equipment used during fire suppression activities can act as pathways for invasive species spread. To prevent the introduction of non-native species, guideline FW-GDL-INV-02 stipulates equipment operated by Forest Service employees and agency-authorized personnel that comes in contact with a water body should be inspected and cleaned for aquatic invasive species prior to use in a water body or when moving between subbasins (HUC08) during non-emergency operation, including pumps used to draft water from water bodies, water tenders, and helicopter buckets. To prevent the spread of invasive species**,** standard FW-STD-WTR-05 requires that when drafting water, pumps, charged hoses, and drafted water shall not be backflushed or discharged into stream channels, wetlands, or other water bodies.

Additionally, all suppression activities would follow protocols outlined in the Guide to Preventing Aquatic Invasive Species Transport by Wildland Fire Operations (National Wildfire Coordinating Group 2017a), the Northern Rockies Coordinating Group Supplemental (Northern Rockies Coordination Group 2018b), and the Northern Rockies Coordinating Group Directive on Aquatic Invasive Species Protocols (Northern Rockies Coordination Group 2018b).

Fire operations would follow industry standards for invasive species decontamination, such as vehicle washing. Rehabilitation efforts after fire suppression operations would help to mitigate many impacts to water resources. Standard FW-STD-SOIL-02 requires impaired soil function created through management activities, including fire suppression, shall be rehabilitated to reestablish soil function to the appropriate site potential. In addition, guideline FW-GDL-RMZ-07 requires restoration of fire suppression activities in riparian management zones and guideline FW-GDL-INV-03 specifies that measures should be used to address invasive weed management when rehabilitating areas burned by wildfire and affected by wildfire suppression. The National Invasive Species Council and Wildland Fire Leadership Council Memorandum (U.S. Department of the Interior 2022a) outlined direction for multiple federal agencies to provide support and resources to the integration and coordination of wildland fire and invasive species management efforts. Effective management of the invasive species and wildfire problem requires increased attention to coordination of invasive species and wildland fire management on the landscape before, during, and after fires. Coordinated strategic planning and leadership across federal agencies and partners help to better identify and address policy needs, budget allocations, operations, response, and monitoring. One strategy encourages the investment in additional resources and capacity to enhance early, aggressive invasive plant management as a preventative measure to sustain resilient and resistant native plant communities and natural wildfire processes and patterns including through interagency and non-federal partnerships.

Meadows, Grasslands, and Shrublands Management

The Nez Perce-Clearwater contains a mosaic of forest, grassland, meadows and shrubland vegetation. Under the Action Alternatives, the meadows, grasslands, and shrublands plan components support native plant communities within the planning area. The Land Management Plan includes six desired conditions that promote meadows, grasslands, and shrublands health (FW-DC-GS-01 to 06). The desired conditions emphasize invasive plant species either are not present or occur with low cover.

Disturbance to ground cover and soil can exacerbate the spread and establishment of invasive plant species. Restoration activities outlined in objective FW-OBJ-SOIL-01 in the soil resource section and objective FW-OBJ-WTR-05 in the water resources section of the Land Management Plan could cause ground disturbance in the short-term but would provide improved conditions in the long-term. To reduce the probability of establishment or expansion of invasive weeds, the Land Management Plan includes guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds. Guideline FW-GDL-SOIL-02 specifies that project activities should provide sufficient effective ground cover, such as litter, fine, and coarse wood material, or vegetation with a post-implementation target of 85 percent aerial extent of an activity area to retain soil moisture, support soil development, provide nutrients, and reduce soil erosion. The depth and distribution of organic matter should reflect the amounts that occur for the local ecological type and natural wildland fire regime. The effects from soil resource management on invasive species establishment would be beneficial for all Action Alternatives.

Aquatic Ecosystems Management

Disturbance to ground cover and soil can exacerbate the spread and establishment of invasive plant species. Restoration activities outlined in the objectives in the water resources section of the Land Management Plan, especially objectives FW-OBJ-WTR-02 and FW-OBJ-WTR-05, could cause ground disturbance in the short-term, but would provide improved conditions in the long-term. To reduce the probability of establishment or expansion of invasive weeds, the Land Management Plan includes guideline FW-GDL-INV-01, which specifies that management activities prone to significant soil disturbance or exposure should be planned and implemented with design features to address the potential spread of invasive weeds. The effects from aquatic ecosystems management on invasive species establishment would be beneficial for all Action Alternatives.

With the action alternatives, the use of herbicides, pesticides, and other toxicants and chemicals would be used within riparian management zones only when the activity does not retard attainment of aquatic and riparian desired conditions (FW-RMZ-STD-03). Further, desired condition FW-DC-TE-02 emphasizes that peatlands, including fens and bogs, have the necessary soil, hydrologic, water chemistry, and vegetative conditions to provide for continued development and resilience to changes in climate and other stressors. These components may limit the treatment methods for some invasive plants in riparian areas and near groundwater dependent ecosystems; for example, hand pulling may be required instead of herbicide use. The herbicides selected for use in these areas would be those that would not alter water chemistry.

Wildlife Management

A variety of wildlife species are known to transport plant seeds or propagules and, thereby, act as pathways for invasive plant species spread. Big game animals can inadvertently transport weed seeds in their fur and hooves, especially during muddy conditions. An increase in big game habitat may, in turn, have a greater potential for weed spread by wildlife.

The wildlife section in the Land Management Plan includes desired condition FW-DC-WLMU-06 that promotes that elk habitat quality is not degraded by invasive species and an objective to treat 500 acres of invasive weeds in elk habitat every 5 years (MA1-OBJ-WLMU-01).

Tribal Trust Responsibilities

The Nez Perce Tribe has ancestral and treaty-reserved rights to uses and resources on the Nez Perce-Clearwater. Indian treaty rights are property rights held by the sovereign Indian tribes who signed the treaties. Under the Nez Perce Treaty of 1855 and subsequent treaties, the Nez Perce Tribe was reserved separate reservation lands, but also retained certain rights to hunt, fish, graze, and gather on the lands ceded to the United States. These rights retained on ceded lands are known as “off-reservation treaty rights” or “other reserved rights.”

Invasive species pose a potential serious threat to the diversity, integrity, and health of native plant communities that are of tribal importance. Invasive plants can reduce the abundance and health of culturally important native plants by invading sacred landscapes, displacing native plants in traditional gathering sites, and stunting or reducing native plant growth or development (Pfeiffer, 2007).

The Land Management Plan includes desired conditions promoting vegetative conditions that provide a sustainable diversity of habitats necessary to provide plant and animal species that are of tribal importance (FW-DC-TT-01) and emphasizing that culturally important botanical species are present and vigorous in quantities that are harvestable and accessible to Nez Perce tribal members (FW-DC-TT-03). Plan components in the terrestrial ecosystems; meadows, grasslands, and shrublands; livestock grazing; and aquatic and riparian livestock grazing sections emphasize the need to support native plant communities and include standards and guidelines to protect important botanical species.

Tribal trust responsibilities could make invasive species treatments more complex. Maintaining tribal trust responsibilities could constrain treatments in particular locations, especially in meadow and riparian areas. The Nez Perce-Clearwater works closely with the Nez Perce Tribe to cooperatively treat invasive species in meadows where known populations of plant species important to the Nez Perce Tribe are present.

Cultural Resource Management

Cultural Resource Management allows for most treatments of invasive species but could require limiting some types of treatment when needing to protect particular physical sites or to preserve ethnobotanical knowledge. Alternative methods of treatment may need to be used but would be determined at the site-specific project level.

Recreation Management

Recreational activities, including non-motorized use, are pathways for potential seed establishment and dispersal. Recreational areas receive concentrated and frequent use, which can increase the potential for ground disturbance. Frequently, infestations are found around trailheads, trails, campgrounds, and other developed and dispersed recreation sites. These seed sources pose a risk of further spread into wilderness and undeveloped lands. Areas located immediately adjacent to and surrounding developed areas tend to experience the most disturbance, while the peripheries of these areas are less disturbed and less likely to be favorable for invasive species establishment and persistence. Generally, wilderness areas and large unroaded lands are less likely to contain invasive weeds due to less widespread public access, especially via motorized means. However, these large unroaded areas are still vulnerable to weed infestation and spread from recreational uses.

In all alternatives, invasive weed prevention measures and public education would be emphasized, including informational signage at trailheads and campgrounds and enforcement of weed free hay requirements for pack and saddle stock. In the Action Alternatives, desired condition FW-DC-ED-01 in the Public Information, Interpretation, and Education section of the Land Management Plan promotes interpretive and educational opportunities that focus on relevant themes, including invasive species.

Access Management

In all alternatives, public motorized and non-motorized travel would continue to be a pathway for invasive species spread along open roads and trails. Motorized travel and use across the Forest are determined by travel plan direction and site-specific project analysis and, therefore, do not vary across alternatives. There are approximately 3,900 miles of system roads and 2,300 miles of trails open to motorized use. There are approximately 3,200 miles of non-motorized trail, primarily used for hiking and horseback riding. About 1,300 miles of these trails are located inside designated wilderness areas.

Roads which are closed or decommissioned would be at risk of invasion by invasive plants until disturbed soils are re-vegetated. Seeding of obliterated roads with native plant seed would continue under all alternatives as they are included in contract specifications.

System Road Management

Maintenance, reconstruction, and construction of forest system roads can contribute to the introduction, establishment, and spread of invasive plant species. New construction of roadways into previously undisturbed plant communities not only creates a suitable seedbed, but in itself acts as an entry point for the seed source. Gravel pits can oftentimes become infested with invasive plants if not routinely checked and treated. Weed seeds can be spread far from the site of origin when gravel is used for road surfacing or other purposes. This potential for invasive plant spread associated with road management activities would generally be the same under all alternatives. There is a potential of increased road work and road use associated with timber harvest and fuels treatments that vary by alternative. Existing weed prevention measures, including cleaning of contracted and government owned road equipment and inspection and treatment of gravel pits, would continue under all alternatives. Gravel pits and main road corridors would continue to be a priority for weed inventory and treatment.

Livestock Grazing Management

Domestic livestock have the potential to transport and spread invasive weed seed, similarly to big game wildlife. Seeds can be spread through livestock feces, fleeces, and hooves, and many can pass through an animal's digestive system and retain the ability to germinate (Belsky and Gelbard 2000).

Areas of livestock concentration, including salting grounds, fence lines, corrals, and water developments, are potential sites for invasive species invasion due to localized soil disturbance. The potential risk of invasive species invasion and establishment due to livestock grazing is the same for all alternatives. Permittees are encouraged in the Annual Operating Instructions to report any new infestations that are found.

In the long term, under the Action Alternatives, livestock grazing management would improve due to plan components associated with the grasslands, meadows, and shrublands; aquatic ecosystems livestock grazing; and the livestock grazing sections of the Land Management Plan. Improved management promotes the enhancement of desirable native plant communities.

Energy and Minerals Management

Energy and minerals activities often cause removal of vegetation and ground disturbance. Additionally, vehicles and equipment can transport undesirable seed to the site. Placer mining and suction dredge mining equipment have the potential to introduce aquatic invasive species.

All energy and mineral management activities on National Forest System lands are required to meet applicable environmental protection measures as required by law, regulation, and policy. Proposed energy and mineral activities require approval of a plan of operations, an environmental analysis, and application of best management practices, including those found in the Manual of Best Management Practices for the Mining Industry in Idaho (Idaho Department of Lands 1992).

Plan components that are common across all Action Alternatives provide direction for restoring mining sites after activities are completed. FW-STD-EM-01 requires new mineral and energy management activities to only be authorized when the associated reclamation plan includes provisions to return disturbed areas to a state of site condition comparable to pre-mineral activity. Any mining activities occurring within riparian management zones require a reclamation plan and bond for full restoration of the site after activities are completed (FW-STD-AREM-01), limitation of new ground disturbance, and removal of roads (FW- GDL-AREM-02).

Proposed desired condition FW-DC-INV-01 seeks to limit the establishment of invasive species to aquatic ecosystems. To move towards this desired condition, prevention measures for aquatic invasive species should be designed and implemented at the project level, such as requiring cleaning and drying of watercraft and equipment before entering a site.

Summary of Environmental Consequences

Table 108 and Table 109 summarize invasive species consequences due to potential soil disturbance potential pathways for invasive plant spread by alternative.

Table 108. Invasive plant summary of consequences due to potential soil disturbance by alternative.

Measurement Indicator	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Timber harvest and fuels treatment average annual acres	4,300	12,600	14,000	7,500	3,700	8,825–10,000
Projected Average Annual Prescribed Fire Acres	14,317	7,345	8,332	8,017	6,451	6,799
Acres of active livestock grazing allotments	612,766	612,766	612,766	612,766	612,766	612,766

Table 109. Invasive plant summary of consequences due to potential pathways for invasive plant spread by alternative.

Measurement Indicator	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Percentage of Forest in summer motorized ROS category	45	47	58	44	43	55
Recreation travel[1]	Baseline	Higher	Highest	Lesser	Lesser	Higher
Timber harvest and fuels treatment average annual acres	4,300	12,600	14,000	7,500	3,700	8,825–10,000
Risk of spread to transitory range due livestock grazing	Moderate	Highest	Highest	Moderate	Moderate	High

[1]Depicts the risk of opportunity for recreation travel to serve as a pathway based on open roads and trails.

Conclusion

As directed by the 2012 Planning Rule, the Nez Perce-Clearwater Land Management Plan includes plan components for integrated resource management to provide for ecosystem services and multiple uses (36 CFR 219.10(a)), while providing plan components that limit the introduction and expansion of invasive species.

Invasive species will continue to have a presence on the Nez Perce-Clearwater landscape. Management under all alternatives would attempt to slow the spread of invasive species and introductions of new invaders. All alternatives provide prevention measures to limit invasive species from establishing into new non-infested areas. Management under all alternatives would continue to follow integrated pest management outlined under Forest Service Manual 2900, which sets forth Forest Service policy, responsibilities, and direction for the prevention, detection, control, and restoration of effects from aquatic and terrestrial invasive species.

The Action Alternatives improve upon the 1987 forest plans for management of non-native invasive species by formalizing current, effective invasive species management practices include plan components that stress the need for management of aquatic invasive species. All alternatives would retain a priority for invasive species management; although the Action Alternatives propose plan components that better emphasize certain aspects of the invasive species management program and offer a more aggressive infestation treatment level. Invasive species under all alternatives would continue to be influenced by changing climates, increased public use, and globalization.

To maintain or improve ecological integrity at the landscape scale, the Land Management Plan includes plan components that provide for opportunities for partnerships to support restoring ecological conditions at the appropriate geographic scale (FSH 1909.12, Chapter 20, Section 23.11b (5)(a)(6). Coordination and collaboration with county weed management officials, other agencies, neighboring national forests, private landowners, and interested groups and individuals would be facilitated through active participation in various cooperative weed management areas, participating agreements, and other initiatives.

3.2.6 Soils Resources

This section addresses soil resource management. Soils are an integral part of ecosystems due to their function in ecological processes and the above and below ground interaction of biological organisms. Since it can take 800 to 1,000 years for one inch of soil to form, it is very important to minimize impacts to the soil resource. The National Forest Management Act states that management activities on National Forest System lands will not produce substantial and permanent impairment of soil productivity. The objectives of current national direction outlined in Forest Service Manual 2500 Chapter 2550 for soils on National Forest System lands are 1) to maintain or restore soil quality and 2) to manage resource uses and soil resources to sustain ecological processes and function so that desired ecosystem services are provided in perpetuity.

Over time, diverse lithology, structure, and climate have resulted in a spatially complex pattern of landforms and soils across the Nez Perce-Clearwater that respond differently to management actions. Most management activities and natural disturbance processes can affect soil resources to varied extents depending on site productivity and recovery. Impacts or signs of stress include surface and subsurface erosion, compaction, lack of ground cover, scarcity of coarse woody debris, high burn severity, or mass movement.

Future management actions could impact or restore the soil resource. By working with the site constraints, management can maintain and, where necessary, restore long-term soil quality, function, and productivity. Soil impairment can be moderated within acceptable limits to ensure sufficient soil recovery and regrowth of vegetation. Soils that are productive and functioning properly are resilient to natural disturbance and human caused stressors, while providing for long-term ecological sustainability.

Comments received since the proposed action and draft environmental impact statement were published have been used where appropriate to improve the Land Management Plan and have helped inform this final environmental impact statement. Multiple minor changes were made for the final environmental impact statement; all changes are within the scope of the draft environmental impact statement analysis and address issues that the public had an opportunity to comment on. With respect to soil resources, there were changes to the soil plan components that were driven from commenters and internal Forest Service suggestions. Also, as a result of public input, an additional alternative was developed called the Preferred Alternative. Analysis of the Preferred Alternative for soil resources is similar to all action alternatives.

Changes Between Draft and Final

Comments received since the proposed action and draft environmental impact statement were published have been used where appropriate to improve the Land Management Plan and have helped inform this final environmental impact statement. Multiple minor changes were made in the final environmental impact statement; all changes are within the scope of the draft environmental impact statement analysis and address issues that the public had an opportunity to comment on. As a result of public input, an additional alternative was developed, called the Preferred Alternative. Analysis of the Preferred Alternative for soils resources is similar to the other action alternatives.

Relevant Laws, Regulations, and Policy

Federal Laws

Multiple-Use, Sustained-Yield Act of 1960 (P.L. 86-517, 74 Stat. 215: 16 U.S.C. 528-531): indicates that a high-level of annual or regular periodic output of renewable resources will be produced on national forest lands while also specifying that "coordinated management of resources will be utilized without impairment of the productivity of the land."

National Forest Management Act (NFMA) of 1976 (16 USC 1604) stipulates to:

- "ensure…evaluation of the effects of each management system to the end that it will not produce substantial and permanent impairment of the productivity of the land" 16 USC 1600, Section 6 (g)(3)(C).
- "ensure that timber will be harvested from National Forest System lands only where- (i) soil, slope, or other watershed conditions will not be irreversibly damaged…" 16 USC 1604 (g)(3)(E).
- "ensure that clearcutting, seed tree cutting, shelterwood cutting, and other cuts designed to regenerate and even-aged stand of timber will be used as a cutting method on National Forest System lands only where…. (v) such cuts are carried out in a manner consistent with the protection of soil, watershed, fish, wildlife, recreation, and esthetic resources" 16 USC 1604 (g)(3)(F).

Forest and Rangelands Renewable Resources Planning Act of 1974: This act provides for maintenance of land productivity and the need to protect and improve soil and water resources.

National Forest Management Act of 1976: This act directs soils to be managed for sustained soil productivity.

Agency Regulations

36 CFR 219.8: requires land management plans to include components to maintain or restore soil productivity, including guidance to reduce soil erosion and sedimentation and to maintain or restore ecosystem integrity (36 CFR 219.8(a)(2)(ii)).

36 CFR 219.19: highlights the importance of soil development, retention, stabilization, and formation in definitions of ecosystem functions and ecosystem services.

36 CFR 219.12: requires monitoring to ensure that management does not substantially and permanently impair the productivity of the land (36 CFR 219.12(a)(5)(viii)).

Policy

Forest Service Manual, Chapter 2550 for Soil Management: directs land managers to "coordinate validation studies of soil quality criteria and indicators with Forest Service Research and Development staff to ensure soil quality measurements are appropriate to protect soil productivity." Six different soil functions are described: soil biology, soil hydrology, nutrient cycling, carbon storage, soil stability and support, and the capacity to filter and buffer environmental contaminants.

Forest Service Manual Northern Region Supplement 2550-2014-1 (U.S. Department of Agriculture 2014o): Regionally, Chapter 2550 was supplemented most recently in 2014 and includes definitions and thresholds for soil monitoring of soil quality related to local conditions. It outlines soil indicators related to disturbance along with thresholds by which disturbance could be severe enough to adversely affect forest growth.

Forest Service Handbook 2509.22: Operationally, the Forest Service mitigates actions using a series of design criteria in projects following standard best management practices, which mirrors many state practices. These practices correspond with more recently produced National Core Best Management Practices (U.S. Department of Agriculture 2012b).

State and Local Laws

Idaho Forest Practices Act of 1974, as amended (Title 38, chapter 13, Idaho Code): The Idaho Forest Practices Act was created to assure the continuous growing and harvesting of forest tree species and to protect and maintain the forest soil, air, water resources, and wildlife and aquatic habitat. The Idaho Department of Lands administers the law and monitors forest activities for compliance. Forest management practices on federal, state, and private lands in Idaho must meet or exceed the requirements of the Idaho Forest Practices Act and complementary administrative rules (IDAPA 20.02.01).

State and Local Plans

Soil and Water Conservation Districts are organized by county. Their efforts are guided by five-year plans containing goals, priority projects, and activities. The five-year plans are associated with management actions on the Nez Perce-Clearwater. However, relevant practices regarding soil management on National Forest System lands are covered by either project mitigations or standard Forest Service best management practices.

Methodology

Spatial and Temporal Scale

This programmatic Land Management Plan analysis focuses on broad scale estimated effects related to soil productivity on National Forest System lands. The analysis area for soils includes all the lands within the boundary of the Nez Perce-Clearwater. This area represents where changes may occur as a direct result of Forest Service management actions. The analysis assumes a time period of roughly 15 years, the life of the plan.

Past, Present, and Future Activities used in the Analysis

Management and public use activities that have affected the soil resource include timber harvest and associated skid trails, landings, temporary roads, and site preparation; fuels reduction activities; prescribed burning; livestock grazing; mining; construction of roads, trails, administration sites, and developed recreation sites; wildfire suppression operations; dispersed camping; introduction of invasive plant species; invasive plant treatment; and off-road motor vehicle use.

Methods and Assumptions

Best available science was used to determine effects of implementing the Land Management Plan to the soil resource. Literature sources that were the most recent, peer-reviewed, and local in scope or directly applicable to the local ecosystem were selected. Uncertainty and conflicting literature were acknowledged and interpreted when applicable.

This analysis takes a programmatic look at the outcomes that may result from implementing the proposed management direction for each alternative over the life of the Land Management Plan. When estimating the effects at the programmatic Land Management Plan level, it is assumed that the types of resource management activities allowed under the action alternatives are reasonably foreseeable future actions to achieve the Forest Service mission. Since future activities' locations are not known at the programmatic Land Management Plan level, specific spatial and temporal effects to soil productivity and function cannot be determined. Therefore, impacts of potential management actions are considered as indirect impacts to soil productivity and function. Cumulative effects from adjacent management of other Forest Service units and state and private entities would not measurably impact soil productivity for this programmatic analysis.

Scientific Uncertainty and Controversy

Soil productivity relies on complex chemical, physical, and climatic factors that interact within the soil. These factors regulate the soil environment that sustains soil microbes and nourishes plants. For any given site and soil, a change in a key soil variable, such as compaction, soil loss, and nutrient availability, impacts potential soil productivity. The rebound after disturbance, such as from erosion or tractor compaction, would depend on climatic context for rebuilding organic matter and soil properties. Soil disturbance on dry sites recover slower than wet sites since rainfall accelerates regrowth of soil microbes and vegetation. This varied site recovery complicates using soil disturbance criteria.

The Northern Region Supplement FSM 2500-2014-1 (U.S. Department of Agriculture 2014o) set policy that the national forest does not create detrimental soil conditions on more than 15 percent of an activity area. The 15 percent threshold was largely based on the collective judgment of soil researchers, academics, and field practitioners and the accepted inability to detect changes in productivity less than 15 percent using current monitoring methods (Powers 1990). The thought was a decline of at least 15 percent was needed to detect a decrease in productivity (Powers 1990). However, the Forest Service does not tolerate productivity declines up to this level but rather recognizes problems with detection limits. The policy does allow for professional judgment by soil scientists to factor in soil type and site recovery.

The Forest Service also initiated a cooperative research project called the North American Long-Term Soil Productivity Study in the early 1990s to better understand soil disturbance impacts on productivity, including understanding site recovery. The study analyzes the effects of soil disturbance intensity against tree seedling growth and investigates the efficacy of soil disturbance proxy for soil productivity. The five- and ten-year results were published in the 2000s (Page-Dumroese and Jurgensen 2006, Fleming et al. 2006, Sanchez et al. 2006). The ongoing Long-Term Soil Productivity Study provides the best available science to resource professionals. At ten years, no observed reduction in tree growth was detected as a result of compaction or organic matter removal in plots with soils generally similar to those found on the Nez Perce-Clearwater (Powers et al. 2005). These results provide short-term insight and involve many site- and soil-specific factors. Forthcoming long-term results, now 25 years on, will provide better information on harvest practice's effects to soil productivity.

The lack of long-term study results and the acknowledgment that soil types recover at different rates to disturbance creates controversy on the judgment of "irreversible damage" as defined in the National Forest Management Act. The National Forest Management Act states to "insure [sic] that timber will be harvested from National Forest System lands only where soil, slope, or other watershed conditions will not be irreversibly damaged." Irreversible commitments of resources equate to the consumption or destruction of nonrenewable resources, such as minerals or cultural resources, or the degradation of resources, such as soil productivity, which can be renewed only over long periods.

Irreversible and irretrievable commitments of resources are defined in Forest Service Handbook 1909.15. Irreversible commitments of resources are those that cannot be regained, such as the extinction of a species or the removal of mined ore. Irretrievable commitments are those that are lost for a period, such as the temporary loss of timber productivity in forested areas that are kept clear for use as a powerline right-of-way or a road. The decisions made in Land Management Plan do not represent actual irreversible and irretrievable commitments of resources. This is because forest planning identifies what kinds and levels of activities are appropriate in different parts of the forest; it does not make project decisions. Ground-disturbing activities cannot occur without further site-specific analyses or project decision documents. Soil personnel would continue to use professional judgment to assess conditions and prescribe treatments to recover soil productivity.

Indicators and Measures

The Land Management Plan analysis compares alternatives that vary the time period and levels to complete similar types of management treatments to move towards desired conditions. Management treatments would primarily impact soils by generating soil disturbance from the mechanical equipment needed to conduct forestry operations.

The following indicators most contrast the affects from the alternatives:

- soil productivity and function, measured by proposed timber harvest acres and proposed soil restoration acres,
- protection of sensitive soils, measured by qualitative assessment of plan components.

The Forest Service defines soil productivity as the capacity to sustain plant communities. Since soil productivity is difficult to measure and varies according to seral stage and site, the Forest Service uses soil disturbance criteria to evaluate soil productivity. These disturbance criteria provide benchmark values that relate to the capacity for soils to function, otherwise called soil quality. If disturbance intensity exceeds established thresholds, then the disturbance is considered detrimental and long-term soil productivity could be potentially impaired. Detrimental soil disturbance is defined by the intensity of compaction, rutting, displacement, severe burning, surface erosion, and mass failure (U.S. Department of Agriculture 2014o). These conditions apply where the Forest Service intends to maintain a productive land base.

Management actions can impact soils by causing soil disturbance or recovery. The capacity of soils can be couched in functional terms: soil biology, soil hydrology, nutrient cycling, carbon storage, filtering and buffering, and the ability to resist erosion and support structures, both from natural and engineering terms. These soil functions become important when restoring soil.

Alternatives were compared using proposed timber harvest objectives and the estimated proportional soil disturbance associated with the activity. Calculations assumed 15 percent detrimental soil disturbance, the high range of disturbance per acre based on Forest Monitoring (Bergstrom 2018). For soil restoration calculations, detrimental soil disturbance rates were used in addition to a 2 percent factor to account for legacy soil impacts within timber harvest units for a net restoration of 17 percent per acre.

Sensitive soils on the Nez Perce-Clearwater have attributes that make them particularly vulnerable to ground disturbance or susceptible to mass movement. Sensitive soil types include grussic soils, hydric wetland soils, severely burned soils, soils with a volcanic ash layer, soils with high erosion potential, and soils prone to mass movement. Management actions can be mitigated on these soil types either by avoidance, incorporation of best management practices, or by limiting the level of soil disturbance from mechanical operations.

Affected Environment

Soil is the primary medium for regulating the movement and storage of energy and water and for regulating cycles and availability of plant nutrients (Quigley et al. 1996). Soils have biological, chemical, and physical properties that are fundamental to the productivity of forest ecosystems and play an integral role in the hydrological behavior of watersheds (Neary et al. 1999). Other resource values, such as water quality and quantity, wildlife habitat, and biomass production are often dependent on and closely related to properly functioning and productive soils. Soils also provide a variety of ecosystem services, such as providing physical support, sequestering carbon, storing and regulating water, cycling nutrients, regulating temperatures, decomposing and filtering waste and toxins, and supporting life (Dominati et al. 2010). It can take hundreds to thousands of years for a soil to develop; therefore, protecting and restoring the soil resource is critical to sustaining ecological processes and functions so that desired ecosystem services are provided in perpetuity.

It can take thousands of years for a soil to develop. Although there are many different soil types, each soil, and its associated properties, is the result of the interaction of the same five factors. These factors are the effect of climate on the parent material, the kinds of plants and organisms living in the soil, the relief of the land, the physical and chemical composition of the parent material, and the length of time it took for the soil to form. Within short distances, the combination of these factors varies, and, consequently, the soils that form differ in fertility, productivity, and physical and chemical characteristics. In mountainous areas, topography and elevation exert strong controls on soil development and productivity. The orographic effects increase moisture to higher elevations while cold temperatures dampen biologic activity. The dissected slopes create microclimates that advance soil formation in concave draws and decrease outward with increasing exposure to sunlight.

The Nez Perce-Clearwater has a wide diversity of soil types from the minimally developed, nutrient poor soil, and rock complexes of the steep mountain slopes and ridges to the deep, fertile soils of the lower valleys. The diverse and productive soils of the Nez Perce-Clearwater are described, characterized, and classified in local soil surveys — Clearwater National Forest Land System Inventory (Wilson et al. 1983), Custom Soil Resource Report for Clearwater National Forest, Idaho (U.S. Department of Agriculture 2014p), and Soil Survey of Nez Perce National Forest Area (U.S. Department of Agriculture and Natural Resources Conservation Service 2007). Data is available digitally through web soil survey (U.S. Department of Agriculture and Natural Resources Conservation Service 2007).

Geologic Time and Parent Material

Most soils on the Nez Perce-Clearwater were formed during the Holocene geological epoch, about 10,000 years ago. The bedrock in the area, which provides soil parent materials upon weathering, was emplaced over much longer periods of time.

The belt supergroup rocks of the Precambrian age (more than 600 million years old) were laid down in a seabed and subsequently metamorphosed. These rocks are mostly schist, gneiss, and quartzite. Metasedimentary rocks form sandy loam, loam, and silt loam textured soils.

The Seven Devils Volcanics were extruded in the southwestern part of the Nez Perce National Forest and are of the Permian and Triassic Age (208 to 286 million years old). These volcanics are intensely folded and faulted metamorphosed rhyolitic rock flows associated with shale and limestone. Rhyolitic rocks are mostly hard, well-fractured andesite. Soil derived from rhyolitic rocks is loamy and contains many hard, angular rock fragments. Subsoil clay accumulations are associated with rhyolitic rocks.

The Idaho batholith granitics intruded into the Belt rocks during the late Cretaceous period (66 to 110 million years ago). The intrusion formed the area’s mountain ranges and resulted in much faulting. Most of these rocks are quartz monzonite, granodiorite, and granite. These rocks weather to sandy loam or loamy sand or to sand. The Belt rock bordering the Batholith was altered and deformed by the intense heat and pressure of the intruding magma. These changed rocks metamorphosed into a variety of mica schists and gneiss and can be found bordering the granitic rocks of the Batholith. More granite and other fine-grained igneous rock were intruded into the existing belt and batholith rocks during early Tertiary time (60 million years ago) and Eocene time (45 to 55 million years ago).

Miocene basalt flows (13 to 25 million years old) overlie portions of the western part of the Clearwater National Forest and the western and southwestern corner of the Nez Perce National Forest. Basalt is a hard, commonly well-fractured bedrock. Soil derived from basalt is loam to clay loam and contains many hard, angular or subangular rock fragments. Soil with subsoil clay accumulations is associated with basalt.

Approximately 100,000 years ago, the climate cooled. Mountain cap and alpine cirque glaciation began sculpting the higher elevations of the Clearwater and Bitterroot Mountains. Most of the high mountain lakes were formed by alpine cirque glaciers during this period. As the climate warmed, the alpine glaciers receded and disappeared around 10,000 years ago.

The active geology across the Nez Perce-Clearwater has facilitated over-steepened slopes that are prone to failure and sediment transport. Wildfire advanced geomorphology by rejuvenating fans and advancing slope formation. The landscape-scale fire events, in particular, explain most of the sediment transport to streams during the Holocene (Kirchner et al. 2001).

Most soils have surface layers formed in loess that has been influenced by volcanic ash. The most significant and influential layer of this loess was deposited on the Nez Perce-Clearwater approximately 6,700 years ago by the eruption of Mount Mazama, or Crater Lake, in Oregon. Additional loess that has been influenced by volcanic ash was deposited by eruptions of Mount Saint Helens and Glacier Peak. These ash deposits range from over 36 inches thick in depressions to very thin deposits that may be mixed with underlying materials on steep southerly aspects at lower elevations to no deposits remaining on the most southerly end of the Nez Perce-Clearwater. The ash deposits produced highly productive soils with excellent water-holding characteristics (Geist and Cochran 1990).

Soil productivity and function

The productivity and function of soil are integral to overall ecological integrity. Human activities or natural events can alter or damage the valuable benefits soil provide. To maintain or improve soil resilience, it is important to use soil ecological knowledge in the management and restoration of the soil resource (Heneghan et al. 2008). Limiting the loss of soil productivity has been the focus of soil management on the Nez Perce-Clearwater since the 1980s. Since 1999, physical soil disturbance has been the focus of soil management on National Forest System lands. With the shift of national policy in 2010, there is now a greater focus on managing National Forest System lands to maintain soil ecological functions as a foundation of planning management actions instead of only focusing on soil disturbance as a proxy for maintaining productivity (Pouyat et al. 2020). The 2012 Planning Rule requires forest plans to include plan components to maintain or restore terrestrial ecosystems, while also providing for ecosystem services and multiple uses.

The Forest Service defines soil productivity as the inherent capacity of the soil resource to support appropriate site-specific biological resource management objectives, which includes the growth of specified plants, plant communities, or a sequence of plant communities to support multiple land uses (U.S. Department of Agriculture 2010b). Since soil productivity is difficult to measure and varies according to seral stage and site, the Forest Service uses soil disturbance criteria to evaluate soil productivity. These disturbance criteria provide benchmark values that relate to the capacity for soils to function, otherwise called soil quality. If disturbance intensity exceeds established thresholds, then the disturbance is considered detrimental and long-term soil productivity could be potentially impaired. Detrimental soil disturbance is defined by the intensity of compaction, rutting, displacement, severe burning, surface erosion, and mass failure (U.S. Department of Agriculture 2014o). Dynamic soil characteristics may be indicators of impaired productivity. Compaction may restrict plant rooting, lower water-holding capacity, and decrease infiltration. Loss of surface soil through displacement and mixing may decrease soil productivity. Displacement occurs during temporary road construction, excavation of skid trails and landings, and displacement of soils during ground-based harvest. Areas with ground disturbance may become more favorable for weed invasion, which can reduce overall soil productivity and quality.

Forest Service Manual 2500, Chapter 2550 defines soil function as any ecological service, role, or task that soil performs, such as soil biology, soil hydrology, nutrient cycling, carbon storage, soil stability and support, and filtering and buffering. These functions support the delivery of ecosystem services. To provide multiple uses and ecosystem services in perpetuity, these six soil functions need to be active and effectively working (Pouyat et al. 2020).

Soil biology is the presence of roots, fungi, and microorganisms in the upper sections of the soil. Diversity of soil biology is beneficial because a complex process of decomposition and nutrient cycling requires a varied set of microorganisms. Also, several organisms are involved in creating and maintaining the soil structure important to water dynamics in soil. Most soil organisms cannot grow outside of soil, so it is necessary to preserve healthy and diverse soil ecosystems to preserve beneficial microorganisms. An increase of invasive species; loss, compaction, or alteration of topsoil layers; and major changes in ground and canopy cover can affect soil biological function.

Soil hydrology is the ability of the soil to absorb, store, and transmit water, both vertically and horizontally. Soil hydrology is extremely important because ecosystem productivity is typically limited by water. Soil can regulate the drainage, flow, and storage of water and solutes, including nitrogen, phosphorus, pesticides, and other nutrients and compounds dissolved in the water. Changes in soil bulk density, soil chemistry, soil structure, soil pores, and ground cover can alter soil hydrology. The main impacts to soil hydrology are compaction, erosion, loss of vegetation cover, loss of ash cap, and hydrophobicity from severe burns.

Nutrient cycling is a supporting ecosystem service and is defined as the movement and exchange of organic and inorganic matter back into the production of living matter. Soil stores moderate the release of and cycles nutrients and other elements. During these biogeochemical processes, analogous to the water cycle, nutrients can be transformed into plant available forms held in the soil or lost to atmosphere or water. Decomposition by soil organisms is at the center of the transformation and cycling of nutrients through the environment. Decomposition liberates carbon and nutrients from the complex material making up life forms and puts them back into biological circulation, becoming available to plants and other organisms. Decomposition also degrades compounds in soil that would be pollutants if they entered ground or surface water. Soil compaction and loss or alteration of organic matter and topsoil can disrupt nutrient cycling.

Carbon storage is a regulating ecosystem service and is defined as the ability of the soil to store carbon. About 23 percent of forest carbon stocks in the Nez Perce-Clearwater are stored in the soil carbon contained in organic material to a depth of 1 meter, excluding roots (Hoang et al. 2019). Organic compounds enter the soil system when plants and animals die and leave their residue in or on the soil. Immediately, soil organisms begin consuming the organic matter; extracting energy and nutrients; and releasing water, heat, and carbon dioxide back into the atmosphere. Thus, if no new plant residue is added to the soil, soil organic matter will gradually disappear. If plant residue is added to the soil at a faster rate than soil organisms can convert it to carbon dioxide, carbon will gradually be removed from the atmosphere and sequestered in the soil. Maintaining organic matter inputs and limiting soil compaction and erosion help to maintain or increase net soil carbon storage.

Soil stability and support are regulating ecosystem services and necessary for anchoring plants, trees, and buildings. Soil is flexible, in that it can be dug, and stable, in the sense that it can withstand wind and water erosion. Inherent soil properties, like soil texture and particle size distribution, play a major role in physical stability. Soil has a porous structure to allow passage of air and water, withstand erosive forces, and provide a medium for plant roots. Management impacts affecting soil stability, and support are those that increase the risk of surface and subsurface erosion, mass movement, and loss of organic matter, including large wood material.

Filtering and buffering by soil are a regulating ecosystem service. The minerals and microbes in soil are responsible for filtering, buffering, purifying, degrading, immobilizing, and detoxifying organic and inorganic materials, including industrial and municipal by-products and atmospheric deposits. Wetlands soils especially function as filters. This function can be impacted by chemical pollutants and industrial contamination at localized sites on the more managed and publicly used portions of the Nez Perce-Clearwater.

Since soil function is difficult to measure in the field, associated indicators that can be readily observed are instead measured. These factors include disturbance to surface organic matter and topsoil. Most management activities affect surface organic matter that can rebound relatively quickly as surface leaf litter and roots in the soil rebuild organic matter stocks. In contrast, the mineral topsoil could be considered a summation of a site's potential to support growth based on bedrock, terrain, climate, and rate of soil development. When management activities displace or remove portions of the topsoil, this impact involves a longer-term recovery than disturbance. These consequences can vary depending on the soil depth and the place in the landscape. Other indicators include soil surface structure, plant species, root growth, mass wasting, and soil compaction.

For additional information, see Management Approaches: Soil Productivity and Function in Appendix 4 of the Land Management Plan.

Natural and Historic Disturbances

Common landscape-scale natural disturbances to soils in terrestrial ecosystems are wildfire, floods, and storms. These natural disturbances act independently and together in affecting surface erosion and landslide processes. Storm events can uproot trees exposing soils to erosion processes. Floods can rapidly remove and replace soils along slopes and in riparian areas. Wildfires combust surface organic matter and forest canopies that are the source of forest duff, creating conditions where bare soil is vulnerable to runoff and soil erosion. Wildfire is common across the Nez Perce-Clearwater, with several largescale events occurring between 1910 and 1934 and more recently in 2012, 2015, and 2017.

High intensity rainfall, along with winter and spring saturating storm events following the fires of the early 1900s, produced high rates of soil erosion. Brushfields along the steep breaklands of the Lochsa River serve as legacy markers of those historic fires.

The natural range of variation for these post fire mass wasting events is diverse, but extremes are relatively rare. Typical patterns for runoff events that trigger mass wasting failure occur roughly every 20 years, although two spring saturating events have occurred in the last 5 years.

Notable human-influenced disturbances include intensive mining in the late 1800s that included hot broadcast burning and hydraulic mining and extensive sheep grazing in which over two million sheep and goats grazed from 1911 to 1953. In more recent history, timber harvest and road construction from 1960 to 1990 created substantial amounts of ground disturbance, which is still evident on the landscape.

Soil Resource Condition and Monitoring

Most soils on the Nez Perce-Clearwater are in a natural condition, particularly in designated wilderness and inventoried roadless areas, which cover approximately 54 percent of the Nez Perce-Clearwater. Soil productivity has been altered to varying degrees where past land use has occurred. These human-caused stressors include timber harvest and associated skid trails, landings, temporary roads, and site preparation; fuels reduction activities; prescribed burning; livestock grazing; mining; construction of roads, trails, administrative sites, and developed recreation sites; wildfire suppression operations; dispersed camping; introduction of invasive plant species; invasive plant treatment; and off-road motor vehicle use.

The greatest impacts to the soil resource have resulted from log yarding and temporary road construction associated with timber harvest. Yarding actions compact and displace soil from skidding logs using ground-based equipment or skyline systems. Road building and landing construction removes surface soil. In addition, actions associated with timber harvest include reduced ground cover, altered vegetative conditions, decreased infiltration rates, increased runoff and surface erosion rates, and diminished site productivity, depending on the intensity and efficacy of operations. While these impacts have not been eliminated in current practices, the Forest Service has decreased these types of effects noticeably through the use of best management practices.

It is estimated that detrimentally disturbed soils occur on approximately 30,000 to 50,000 acres on the more managed portion of the Nez Perce-Clearwater. Detrimental effects on soils are not always permanent with regards to soil function and vegetation re-growth and depend primarily on soil texture, parent material, aspect, and the level of disturbance. Although recovery time is typically between 30 and 70 years (Froehlich and McNabb 1983, Froehlich et al. 1985, Dykstra and Curran 2002), loss of ash in areas where the ash augments the growing environment could see longer recovery rates. As discussed in (Williamson and Neilsen 2000), forest management has changed in the last few decades due to the development of new technologies, as well as a better understanding of the ecological impacts of management actions.

Soil monitoring on the Nez Perce-Clearwater has primarily targeted timber harvest operations. Monitoring ensures management actions maintain site productivity by limiting detrimental soil disturbance and complies with the Clearwater National Forest Plan (U.S. Department of Agriculture 1987a), the Nez Perce National Forest Plan (U.S. Department of Agriculture 1987b), and the Northern Region Supplement FSM 2500-2014-1 (U.S. Department of Agriculture 2014o).

In 2008, a field review was conducted on four timber sales on the Clearwater National Forest that covered a variety of soil types and logging systems (Archer 2008). Results found that soil conditions following timber harvest depended on the harvest system used and the subsequent site preparation of slash materials. Skyline yarding resulted in the least detrimental soil disturbance compared to tractor systems. For tractor yarded units, soil moisture, the type of site preparation, and operator efficacy were the biggest factors in soil disturbance. Skyline harvest led to a 0 to 7 percent detrimental soil disturbance, with most of the disturbance from severe burning during site preparation following harvest. Tractor harvest led to 8 to 22 percent detrimental disturbance after harvest and site preparation activities. Site preparation treatment disturbance was from broadcast burning or excavator piling and follow-up pile burning.

In 2009, post-harvest soil surveys on the Clearwater National Forest were conducted on 11 ground-based harvest units and 10 skyline units; all surveys were harvested during the summer under dry conditions (Reeves et al. 2011). Results showed skyline systems led to 1 percent detrimental soil, while ground based harvest systems led to approximately 13 percent detrimental soil disturbance.

Between 2011 and 2017, post-activity soil disturbance was monitored on 140 activity units associated with 24 timber sales on the Nez Perce-Clearwater (Bergstrom 2018). This effort resulted in approximately 3,200 acres being assessed using the national soil disturbance monitoring protocol (Page-Dumroese and Jurgensen 2006). Analysis of the over 11,000 monitoring points resulted in a mean detrimental soil disturbance of 7 percent, with a range of 0 to 37 percent. In addition to determining the amount of soil disturbance, estimates of the areal density of coarse woody debris were carried out in the same activity units.

Some of the monitoring conducted from 2011 to 2017 collected data specific to the type of logging system used for harvest. Post-harvest soil disturbance monitoring occurred on 45 units that were logged using ground-based equipment and on 19 skyline units. Results showed that detrimental soil disturbance ranged from 0 to 10 percent using skyline harvest systems and 0 to 29 percent using ground-based systems. Mean values for detrimental soil disturbance associated with ground-based systems and skyline systems were 9 percent and 3 percent, respectively. Ground based harvest units with 0 percent detrimental soil disturbance were harvested over snow or the units were small, requiring only one pass with skidding equipment. Ground based harvest units with a higher percentage of detrimental soil disturbance often included soil impairment from previous harvest entries.

Regional direction (U.S. Department of Agriculture 2014o) for organic material recommends following guidelines outlined in Graham et al. (1994), which recommends maintaining between 7 to 33 tons per acre of coarse wood material depending on habitat type, moisture regime, and aspect. Post activity monitoring from 2011 to 2017 found coarse wood levels were overall low, with 33 percent of the harvest units meeting minimum coarse wood thresholds. Overall monitoring showed an average of 7 tons per acre and ranged from 0 to 55 tons per acre. Although Keane et al. (2013) found the methods to calculate coarse wood material imperfect, the monitoring data indicates a trend of coarse wood levels below recommended amounts following post-harvest and site preparation activities. Notably, units with previous harvest were low in coarse wood material to begin with, primarily due to historic slash disposal methods. In the past, slash material was removed with high intensity broadcast burning or piled with bulldozers, taking all organic matter and topsoil with it.

Based on Forest Service data collected through Forest Inventory and Analysis (FIA), current forestwide coarse wood material is within the ranges prescribed for each potential vegetation type (Table 110). The desired condition ranges were calculated using the coarse woody debris recommendations by habitat types in Graham et al. (1994) and correlated to potential vegetation type.

Table 110. Existing coarse wood material (in tons per acre) forestwide, by potential vegetation type.

Potential Vegetation Type	Desired Condition	Existing Condition[1]
Warm Dry	7-15	10
Warm Moist	17-33	17
Cool Moist	9-18	13
Cold	7-24	9

[1]Estimates are expressed within a 90 percent confidence level.

Data Source: Forest Inventory and Analysis data collected 2011 to 2017.

Soil productivity relies on soil organic matter, which is influenced by wildland fire, harvest activities, decomposition, and accumulation rates. The organic component of soil is a large reserve of nutrients and carbon and is the primary site for microbial activity. Forest soil organic matter influences many critical ecosystem processes, including the formation of soil structure. Soil organic matter is also the primary location for nutrient recycling and humus formation, which enhances nutrients, water storage, and overall fertility. Soil organic matter depends on inputs of biomass, such as vegetative litter and fine woody debris, to build and maintain the surface soil horizons, support soil biota, enhance water-holding capacity, and prevent surface erosion. Much of the nutrient capital on soils on the Nez Perce-Clearwater depends on forest floor, coarse wood debris, and organic matter in the topsoil.

The impacts from forest management continue to be offset by best management practices that either avoid or minimize the intensity of timber harvest operations. Additionally, over the past 20 years, active restoration of soils has facilitated a more rapid recovery of soil function. Since the early 2000s, the Nez Perce-Clearwater has actively restored temporary roads associated with timber harvest units. Restoration actions include decompacting soils, recontouring slopes, and adding organic matter to improve soil conditions and accelerate recovery. Beginning in 2012, due to the success of the Nez Perce-Clearwater system road decommissioning program, several timber harvest projects included design measures to restore detrimental soil disturbance on skid trails and landings, in addition to temporary roads. The design measures required treatment methods similar to those used in the Nez Perce-Clearwater system road decommissioning program.

Decommissioning of system roads started on the Nez Perce-Clearwater in the mid-1990s. On the Clearwater National Forest, road decommissioning projects were routinely monitored, and treatment techniques improved over time by using adaptive management. Methods have been shown to improve soil structure and soil porosity based on road decommissioning monitoring on the Clearwater National Forest. Local research by Lloyd et al. (2013) found similar techniques improved infiltration rates and soil bulk densities to values similar to never-roaded areas at 1, 5, and 10 years following decommissioning. In this same study and timeframe, soil organic matter, total carbon, and nitrogen pools and processes increased to levels similar to never-roaded surfaces. Across a range of sites, a Clearwater Forest Plan Monitoring Report (U.S. Department of Agriculture 2009d) documented an increase in vegetative cover from 18 percent the year after decommissioning to 64 percent 10 years after decommissioning. Since the mid-1990s, the Nez Perce-Clearwater's watershed restoration program has obliterated hundreds of miles of historic harvest-related skid trails and non-system roads. Between 2005 and 2018, the Nez Perce-Clearwater treated approximately 840 acres within harvest units, while approximately 14,000 acres of legacy non-system roads, such as jammer roads, were treated outside of harvest units.

Sensitive Soils

Disturbance from wildfire and anthropogenic land management can have a disproportionate effect on soils, resulting in poor recovery. Sensitive soils have characteristics that vary from higher susceptibility to compaction, being prone to soil erosion after loss of ground cover, and having the majority of nutrient base stored in the topsoil. The soils and conditions listed below outline most of the sensitive soils and conditions found across the Nez Perce-Clearwater.

Granitic Soils

Grussic soils weather from granitic bedrock that produces many fine, gravel-sized particles of weakly consolidated rock. Approximately half the Nez Perce-Clearwater has granitic bedrock. However, weathered grussic soil occurs on roughly four percent of the Clearwater National Forest, equaling 165,000 acres, based on Clearwater landtype information (Wilson et al. 1983). Particles from the weathered rock are easily crushed between fingers demonstrating the erodible nature. Bared or disturbed subsoils where this grussic soil is exposed easily erode and are highly susceptible to mass wasting. Once exposed, the loose substrate does not revegetate readily. The loose aggregate produces extremely well drained conditions but results in droughty soils and poor fertility. Thus, the surface organic layers on grussic soils have higher proportional fertility than typical forest soils.

Hydric Soils

The National Technical Committee for Hydric Soils defines hydric conditions as formed under saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions in the upper part of the soil profile (U.S. Department of Agriculture 2018j). These soils either saturate or inundate long enough during the growing season to support the growth and reproduction of hydrophytic vegetation. Hydric soils are a primary indicator of wetlands and are used to assess compliance with Executive Orders 11988 and 11990, directives relative to the management and disposition of floodplains and wetlands. Hydric soils occur across the Nez Perce-Clearwater in floodplains, wetlands, meadows, and adjacent to isolated springs and seeps. These wet conditions are more prone to rutting and compaction from equipment.

Severely Burned Soils

Wildfire, natural fuels prescribed burning, and site preparation burns following timber operations have the potential to severely burn soils. These soils have higher sensitivity to ground disturbance because of the change in soil biological and physical properties. Soil burn severity is the effect of a fire on ground surface characteristics, including char depth, organic matter loss, and altered color and structure (DeBano et al. 1998). Soils with high burn severity become more vulnerable to compaction due to loss of soil structure and can erode more readily from lack of soil cover and reduced ability to infiltrate rainfall.

Severely burned soils are identified using the Field Guide for Mapping Post-Fire Soil Burn Severity (Parsons et al. 2010). Recovery of severely burned soils depends on the inherent productivity of a site and is based on factors such as soil type, available water, and adequate temperature for growth. Wildfires typically result in 4 to 10 percent high soil burn severity, while prescribed fires generally create less burn severity because burning often occurs during cooler and more moist conditions (U.S. Department of Agriculture 2013b). Soils recover more slowly where severely burned. A western Montana study showed high burn severity areas revegetated within 10 years compared to quicker rates in areas with low and moderately severe burns (Lewis et al. 2017).

Site preparation of timber harvest units typically includes broadcast burning or excavator piling and follow-up pile burning. Site preparation burns range from 1 to 3 percent severely burned soil based on Clearwater National Forest monitoring (Archer 2008). Detrimental soil conditions within burn pile scars can persist for several decades due the concentrated heating (Jiménez Esquilín et al. 2008, Rhoades and Fornwalt 2015).

Mass Movement Soils

Soil mass movement is defined as the detachment and downslope movement of soil or the surface mantle in the form of debris slides or avalanches or deep-seated rotational failures or slumps (U.S. Department of Agriculture 2014o). Landslide is the general term used to describe mass movement events including slides, slumps, soil creep, debris flows, topples, and falls of soil and rock. Landslides most likely re-occur in the same location because of geologic bedrock orientation and contacts. In the steep topography so prominent in the river country of the Nez Perce-Clearwater, soil mass movement is a natural disturbance process. However, periodic, sufficient-sized storms have the potential to induce mass movement in areas that received stand replacing burns (Meyer 2001), as well as unburned areas when sufficiently saturated

(McClelland et al. 1997). Warm weather fronts during winter and spring can quickly melt snow that supersaturates slopes, causing subsequent failure. During these conditions, concave hollows concentrate moisture that can produce debris flows (Wondzell and King 2003).

Currently, potential mass failure is described as landslide prone in the 1987 Nez Perce and Clearwater National Forest Plans. The Nez Perce National Forest defines landslide prone as areas with slopes steeper than 60 percent and with mapped landslide deposit landtypes (U.S. Department of Agriculture 2007a). The Clearwater National Forest defines landslide prone terrain (U.S. Department of Agriculture 2007a) based on a slope break of 55 percent and the landtype 50 series, which are slump and earthflow landtypes (Wilson et al. 1983). Together, landslide prone areas were mapped on approximately 857,000 acres, covering approximately 22 percent of the Nez Perce-Clearwater.

Because such a coarse filter was used to predict landslide potential, areas with proposed harvest and prescribed burn activities are field surveyed to verify risk and determine actual extent of mass movement potential. Characteristics of unstable slopes include wetland areas and moist seeps situated on slopes; hydrophytic vegetation, indicating saturated soil conditions during at least a portion of the year; slumps, soil creep, hummocky or benched surfaces, especially below crescent-shaped headwalls; headwall scarps, tension cracks, curved or buttressed tree boles; and back-rotated, jack-strawed, pistol-butted, or leaning trees.

During storm and flood events in 1995 and 1996, over 860 landslides occurred across the Clearwater National Forest. Most landslides were triggered by a heavy rainfall season with rain-on-snow events. Over half of the landslides documented were associated with roads. Based on a review of the landslides, McClelland et al. (1997) identified five factors to assess landslide potential: geologic parent material, elevation, aspect, slope angle, and landform. The highest landslide prone erosion potential occurs on border zone metamorphic parent materials; less than 2,000 to 4,000 feet elevations; south and southwest aspects; greater than 56 percent slope angles; and mass wasted slopes and breakland landforms.

Highly Erosive Soils

Soils that have a high or very high erosion potential are also considered sensitive. Soil erosion hazard potential is classified by landtype and subdivided by erosion type, which includes surface erosion, mass wasting, and subsurface erosion. Surface erosion follows disturbance events that remove groundcover, such as wildland fire or after timber harvest. Landtypes help distinguish which areas are predisposed to higher erosion risk. Landtypes are given ratings of low, moderate, high, and very high depending on characteristics such as parent material, slope, aspect, and landform. As the rating increases the potential risk of erosion also increases. Soil erosion affects soil quality, function, and productivity and can be delivered to streams, affecting water quality and fish habitat. Landtypes and associated erosion hazard ratings were mapped across the Nez Perce-Clearwater, minus wilderness areas. Table 111 shows the percentage of the mapped areas occurring on landtypes with high or very high erosion hazard potential by erosion type. Using the landtype mapping, 17 percent of the Nez Perce-Clearwater has conditions that could potentially have high and very high erosion hazard. Roughly 24 percent of the Nez Perce-Clearwater has subsoils that could have high or very high erosion hazard when bared during road construction. It should be noted that erosion hazard is minor when these soils have natural forest ground cover.

Table 111. Percent of mapped landtypes with high or very high erosion hazard potential, by erosion type and evaluation for rating.

Erosion Type	Evaluation for rating	Percent Mapped Area
Surface erosion potential	Considers raindrop splash and overland flow erosion on soils bared of vegetation but retain the root mat and soil structure. This potential is used for predicting surface erosion following wildland fires. The presence of the Mazama volcanic ash cap plays an important role in surface erosion potential since this material is extremely permeable, has a high-water holding capacity, and is seldom associated with overland flow.	17
Mass wasting potential	Considers the relative potential for mass soil movement caused by gravitational forces. It involves the movement of regolith as a coherent mass along a slippage plane created due to subsurface water concentration.	22
Subsurface erosion potential	Considers raindrop splash and overland flow erosion where the subsoil has been exposed or where the surface soil has been severely disturbed and mixed with the subsoil.	24

Data Source: (Wilson et al. 1983, U.S. Department of Agriculture 2007a).

Erosion hazard mapping has advanced since the initial efforts in the 1980s. At the project level, managers can now spatially determine erosion hazard rates and amounts. The landtypes provide a broad view context, whereby actual risk depends more on slope, groundcover, soil type, and the storm event (Wondzell and King 2003, Elliot 2013).

Ash Cap Soils

Soil with a surficial volcanic ash deposit, or ash cap, is another group of sensitive soils and are instrumental to the high productivity of the Nez Perce-Clearwater. Using forest mapping, ash soils cover approximately 825,000 acres, or 20 percent of the Nez Perce-Clearwater, and increase in depth to the north and west. Ash occurs from 1,000 to 5,900 feet in elevation (Kimsey Jr 2006).

Volcanic ash is composed of angular shards of glass. If these angular pieces remain undisturbed, they settle and become interlocked forming a very cohesive layer that is resistant to weathering. These soils are characterized by a low bulk density, high water holding capacity, and high cation exchange capacity that can lead to a concentration of nutrients.

The primary ash topsoil was laid down 7,700 years ago by volcanic eruptions from Mount Mazama and to a lesser degree, recent eruptions from Mount Saint Helens and Glacier Peak (McDaniel et al. 2018). The original deposit was 1 to 2 feet thick, with most accumulation either in depressions or areas protected from erosion (Wilson et al. 1983). Much of the ash has either eroded away or mixed with topsoil. Ash becomes rare on many steep southerly aspects or on high elevation areas that have experienced historic, high intensity wildfires (Wilson et al. 1983). Where present, volcanic ash has increased soil productivity due to high water holding capacity and resistance to erosion.

The ash deposited on the Nez Perce-Clearwater tends to have fine particles forming loam and silt loam textured soils. The high-water holding capacity is arguably the most important feature of the ash cap locally. The ash was deposited over rocky and sandy coarse textured soils with relatively low water holding capacities in north and central Idaho and, therefore, the majority of the plant-available water in this landscape is held in the ash cap. The presence of thick ash can sustain growing conditions beyond what otherwise the climate would limit.

Soil surface layers formed in ash and loess are an excellent medium for plant growth. Soils with the thickest loess surface layers tend to be the most productive. An ash-influenced surface layer resists erosion when undisturbed but, once bared and compacted, can have higher risk for soil loss. Ash caps are extremely susceptible to decreased soil quality due to compaction, erosion, and soil mixing (Page-Dumroese et al. 2007). Ashy soils do not recover from compaction as quickly as other soil types. Since volcanic ash is not replaced, the effects of erosional losses of the ash cap can be permanent.

Shallow and Infertile Soils

Shallow soils have a depth less than 20 inches deep and are susceptible to erosion and detrimental effects from management actions because of inherently low fertility due to carrying much of the productive capacity in the thin topsoil. These soils generally have weak development, relatively little organic matter, and, therefore, have low nutrient levels. Soil displacement and loss disproportionately affects productivity. Furthermore, shallow soils have higher erosion risk since runoff can concentrate laterally along the interface between the bedrock layer and soil material.

The existing forest plan Standard 5 in the Clearwater Forest Plan calls attention to potential erosion and productivity loss on shallow infertile soils and compacted till in the Powell area. The latter case is a concern because of raised water tables where transpiration decreases from tree removal. The higher water table could exacerbate soil piping, sloughing, and overall erosion loss.

The over-steepened slopes common on the Nez Perce-Clearwater produce many areas with shallow, nutrient poor soils. These soils tend to be on south facing slopes, along steep breaklands that adjoin streams and rivers, and along alpine ridges and glacial carved side slopes. Soil mapping underestimates these shallow soils at 152,000 acres, largely because mapping is poor in the steep, rocky wilderness areas where soils have higher glacial influence and rock outcrop.

Environmental Consequences

The land management plan provides a programmatic framework that guides site-specific actions but does not authorize, fund, or carry out any project or activity. Because the land management plan does not authorize or mandate any site-specific projects or activities, including ground-disturbing actions, there can be no direct effects. However, there may be implications, or longer-term environmental consequences, of managing the Nez Perce-Clearwater under this programmatic framework.

The environmental consequences analysis for the soils resource focuses on timber harvest associated activities that have measurable impacts to soils over the next planning cycle on National Forest System lands within the administrative boundary of the Nez Perce-Clearwater. Other management activities, such as livestock grazing, dispersed camping, invasive plant treatment, prescribed fire, fuels treatments, and fire suppression operations, can also cause ground disturbance and detrimentally impact soils. The scale of the disturbance is small enough and distributed such that comparisons between the alternatives would only be slight. Thus, the effects of these activities are only discussed in the Effects to Soil Resource from Other Resources.

Effects Common to All Alternatives

The potential impacts from climate change to soil resources would be the same for all alternatives. Changes in climate, coupled with an increase in the frequency and severity of extreme weather events, have had, and will continue to have, direct and cascading indirect effects on soil formation and associated productivity rates, as well as physical, chemical, and biological processes (Pouyat et al. 2020). Shifts in precipitation patterns, temperature increases and variability, and increases in atmospheric carbon dioxide (CO_2) concentrations affect plant productivity, flooding, nutrient cycling, and biological populations. Changing conditions that result from a warming climate, such as increased wildfire potential and invasive species expansion, will have an impact on soil function, long-term ecological sustainability, and the ability to provide ecosystem services. Increasing air temperature, through its influence on soil moisture, is expected to cause gradual changes in the abundance and distribution of tree, shrub, and grass species, with more drought tolerant species becoming more competitive (Halofsky, Peterson, et al. 2018a). Climatic changes are expected to differentially affect tree species and their distribution on the landscape, as well as some of the pathogens that act upon them (Keane et al. 2018). There is also significant concern that climate change effects combined with altered disturbance regimes caused by fire exclusion will change ecosystems (Hessburg et al. 2005).

The relationship between soil and anthropogenic climate change is twofold. First, climate change may affect the soil resource and how it functions. Second, soil can either store or release greenhouse gases, thereby potentially influencing climate change. The potential impacts of climate change on the forest soil resource are not well known at this time. Warmer and wetter winters may result in large areas of reduced trafficability for winter harvest operations, a common soil protection practice on the Nez Perce-Clearwater. Increased frequency and severity of summer droughts could threaten effective vegetation cover through increased wildfire, insect and disease activity, and spread of non-native plants (Halofsky, Peterson, et al. 2018a, b). Soil erosion is tied to many forces on the landscape that are affected by climate change. In mountainous areas, wildfire and precipitation interact to affect erosion rates. Frequency of wildfire, precipitation in the form of rain rather than snow, and intense precipitation events are expected to increase a combination that will lead to greater erosion and more landslides (Halofsky, Peterson, et al. 2018b). Expansion of invasive species may also reduce soil biota diversity.

Literature suggests that opportunities may exist to manage the soil carbon pool (Harmon and Marks 2002, Johnson and Curtis 2001, Yanai et al. 2003). However, predicted soil carbon response to anthropogenic climate change is extremely uncertain at this time (Friedlingstein et al. 2006, Todd-Brown et al. 2013). Carbon sequestration will be increasingly difficult if wildfires, insect outbreaks, and perhaps plant disease increase as expected, especially in the western part of the Northern Rockies. At the same time, managing forests for carbon sequestration is likely to become more important in response to national policies on carbon emissions (Halofsky, Peterson, et al. 2018a).

Effects of the No Action Alternative

Since the Nez Perce and Clearwater National Forests administratively combined in 2012, it has been difficult to provide consistent soil management administration across the combined Nez Perce-Clearwater because the direction from the two forest plans differed. This inconsistency mainly impacts forest management planning and implementation. The two plans also do not have the same avoidance mitigation for sensitive soils. This is particularly poignant on excluding landslide prone areas. The plans similarly do not have adequate criteria for conserving organic materials after timber harvest and fuels treatments. Current planning efforts rely on contemporary studies for recommendations on coarse wood retention. Finally, both 1987 plans do not clearly articulate restoration activities that have evolved since the 1980s. Rather, the Plans focus on avoidance and minimization and not on active reclamation to maintain and improve existing soil conditions.

Soil impacts from timber harvest operations may not noticeably differ between the Nez Perce and Clearwater since implementation uses common contract language and best management practices. However, plan differences can influence decisions on where and how to conduct forest management between the two national forests. One example is that the Clearwater National Forest has more flexibility when managing past harvest areas with extensive past disturbance. On the Nez Perce portion, the forest plan caps detrimental soil disturbance at 20 percent, while the Clearwater National Forest relies on the Northern Region Supplement 2500-2014-1 (U.S. Department of Agriculture 2014o). To ensure compliance with Standard 1 in the Clearwater National Forest Plan, the forest limits the amount of detrimental soil disturbance to 15 percent of an activity area, consistent with the Northern Region

Supplement FSM 2500-2014-1. The Northern Region Supplement FSM 2500-2014-1 allows for improving soil condition when existing soil disturbance exceeds 15 percent areal coverage (U.S. Department of Agriculture 2014o).

Timber harvest and associated actions would continue as the management activity that produces the highest amount and level of ground disturbance. Timber harvest and associated actions can remove or modify ground cover and surface organic material; remove or modify topsoil or the volcanic ash layer through soil erosion, displacement, compaction, rutting, mixing, or severe burning; expose or mix subsoil; and increase mass movement potential. Since there is no requirement for soil restoration, detrimental soil disturbance from historic activities would remain. Restoring soils after timber harvest occurs on some projects but is not required.

Soil restoration outside of timber harvest units is conducted through the watershed restoration program, primarily as non-system road decommissioning. This activity would still occur under the No Action Alternative as long as the Nez Perce-Clearwater continues to prioritize watershed restoration activities.

Soil productivity and function

The primary management strategy over the last few decades is limiting activities that detrimentally disturb soils. Since timber harvest and associated activities tend to create the most soil disturbance, it is the focus of the soils effects analysis. On both national forests, detrimental soil disturbance is calculated using the national soil disturbance monitoring protocol (Page-Dumroese et al. 2009b, a).

Standard 1 in the Clearwater National Forest Plan requires bulk density measures, which have high costs in time and money. Since 1999, the Clearwater has used soil detrimental disturbance, as defined in the Northern Region Supplement FSM 2500-2014-1 (U.S. Department of Agriculture 2014o), as a proxy and limits the amount of detrimental soil disturbance to 15 percent of an activity area. In areas already exceeding 15 percent, detrimental soil disturbance and ground disturbing activities are allowed if treatments restore soil and leave a net improvement in soil quality.

The Nez Perce National Forest Plan Standard 2 limits detrimental soil disturbance to 20 percent of an activity area using similar indicators as those described in the Northern Region Supplement FSM 2500-2014-1 (U.S. Department of Agriculture 2014o). However, this has become problematic, as it is less restrictive than the regional guidance and it does not offer the ability to conduct ground disturbing actions on areas over 20 percent even if soil restoration is included. Site specific amendments to the Nez Perce Plan have occurred to enter areas exceeding 20 percent detrimental soil disturbance, thus allowing for multiple resource objectives while showing an upward trend in net soil conditions through soil restoration.

Additional issues relate to the need to harvest timber in areas with legacy soil disturbance. Over the last planning cycle, due to forest succession, silviculture has increasingly proposed treating stands previously harvested in the 1950s and 1960s. Because historic harvest methods created higher soil disturbance, the effects to soil productivity persist. In many instances, the summation effects of proposed harvest and existing detrimental soil disturbance becomes difficult to remediate to levels compliant with either the Clearwater or Nez Perce 1987 plans. Some timber sale projects have included soil restoration to achieve a net decrease of detrimentally disturbed soil to meet forest plan standards. Unfortunately, post-harvest surveys using the national soil disturbance monitoring protocol (Page-Dumroese et al. 2009b, a) indicate that the restored soils are still technically considered determinately disturbed by definition. For example, a temporary road that was uncompacted, fully recontoured, and overlaid with organic material receives the same detrimental disturbance rating as a road not treated, despite the treatment having improved soil functions. In this example, the restored temporary road is far more productive than the untreated road.

Other current soil management not included in the existing forest plans but included as design features in projects to meet the intent of the standards include:

- Avoidance of ground disturbance or removal of trees on landslide prone areas, which includes areas over 55 to 60 percent slope, as defined in an earlier forest plan revision process (U.S. Department of Agriculture 2007a) and as required by PACFISH and INFISH.
- Limitation of ground-based harvest systems to slopes less than 35 percent, unless exempted by field review by a soil scientist.
- Retention of downed wood material as recommended by Graham et al. (1994).
- Utilization of timber sale contract provisions, national core best management practices, regional soil and water conservation practices, and adherence to Idaho Forest Practices Act guidance.

Plan direction does not provide contemporary environmental controls that reflect changes in logging systems. For example, the soil standards in both 1987 plans do not designate slope steepness. Instead, project design measures require operations limit ground-based equipment to less than 35 percent except for short pitches. The measure is conservative and does not consider new equipment technology and logging systems updates. Potentially ground-based harvest could operate on steeper slopes without the adverse soil effects reflective of past dated equipment.

Finally, the Land Management Plan direction does not include adequate criteria for maintaining soil organic matter. Soil organic matter is extremely important in regulating soil function for plant nutrition and water (Jurgensen et al. 1997). In these primarily montane soils, the forest floor and thin topsoil makes up a large proportion of the productive capacity. Page-Dumroese and Jurgensen (2006) outlined the variable amounts of nitrogen and carbon – two essential elements for productivity – in habitats that cover the Nez Perce-Clearwater. Their work underscores the importance while also giving baselines for these important nutrients. Similarly, research was completed during the last planning cycle that gives explicit ranges for coarse wood debris (Graham et al. 1994). These recommendations acknowledge the strong above ground and below ground connections between ecto- and endo-mycorrhizae for tree and understory growth (Harvey et al. 1987, Perry et al. 1989). These recommendations endure due to the long-term work that went into describing these ranges and the re-enforcement by more recent research of explicit connections across tree fungal networks.

Protection of sensitive soils

The Nez Perce National Forest has a general plan component to avoid erosion while the Clearwater National Forest has four specific plan components to address damage to ash soils and soil loss from erosive conditions and unstable environments. These discrepancies complicate compliance across the Nez Perce-Clearwater for sensitive soils. One of the most important conditions that causes confusion is landslide prone. The action alternatives would standardize this approach and would provide better over-arching protection.

Effects Common to Action Alternatives

Desired conditions in the Land Management Plan provide a vision of the future landscape and serve to focus management attention by describing the specific desired ecological characteristics of soil resources within the plan area towards which management of the land and resources would be directed. Standards and guidelines are designed to protect soil resources when conducting activities that might affect them.

Because desired conditions, standards, and guidelines for soil resources do not vary between action alternatives, any differences in the indirect effects to soil resources would be based on variation of the action alternatives for the soil resources objectives and projected amounts of other land management activities.

The effects analysis evaluates the relative ability of the proposed action alternatives to improve or decrease soil productivity and function. Many land management activities carried out on the national forest have the potential to adversely affect soil resources to some degree. The plan components within the soil resource section of the Land Management Plan are consistent across all action alternatives. Additionally, the Land Management Plan includes a monitoring plan that would track the effectiveness of implementing the Land Management Plan and a management approaches section that offers possible strategies the Nez Perce-Clearwater could undertake to maintain or make progress towards achieving the desired conditions described in the Land Management Plan.

The effects analysis primarily focuses on management activities that occur in the more managed portion of the Nez Perce-Clearwater, which is delineated as Management Area 3 and covers 1,240,340 acres under the Preferred Alternative resulting in approximately 30 percent of the Nez Perce-Clearwater. Management Area 3 is described as the "front country" and consists of the areas with roads, trails, and structures, as well as evidence of past and ongoing activities designed to actively manage the area. The rest of the Nez Perce-Clearwater is split into Management Areas 1 and 2 lands where more natural ecological and disturbance processes occur, and soil resources are generally considered to be within the natural range of variation. Management Area 1, consisting of approximately 1,231,638 acres for the Preferred Alternative, contains designated wilderness, designated wild and scenic rivers, and National Historic Landmark areas. Management Area 2 encompasses approximately 1,467,078 acres for the Preferred Alternative and includes lands within Idaho Roadless Areas, recommended wilderness areas, suitable wild and scenic rivers, parts of the Gospel-Hump Geographic Area, and proposed and designated research natural areas.

The objectives of current national direction on National Forest System lands are 1) to maintain or restore soil quality and 2) to manage resource uses and soil resources to sustain ecological processes and function so that desired ecosystem services are provided in perpetuity (U.S. Department of Agriculture 2014o). The Nez Perce-Clearwater proposes to focus soil management on these objectives and move away from the current disturbance tracking as described in the No Action alternative. The Nez Perce-Clearwater plans to continue using soil resource information for designing projects since soils give vital information on vegetation growth. The action alternatives would continue to rely on soils resource specialists for project planning. The engagement of soils specialists in projects would ensure soil management objectives. The Nez Perce-Clearwater would continue stewarding soils resource layers as part of the national cooperative soil survey.

The 2012 Planning Rule requires Land Management Plans to include plan components to maintain or restore soils and soil productivity, including guidance to reduce soil erosion and sedimentation (36 CFR 219.8(a)(2)(ii). This requirement supports long term ecological sustainability.

All the action alternatives propose the following desired conditions based on the understanding of natural disturbance regimes and ecosystem processes:

- FW-DC-SOIL-01. Soil productivity and function contribute to the long-term resilience of ecosystems.

- FW-DC-SOIL-02. Soil organic matter and downed woody material support healthy microbial populations, protect soil from surface erosion, facilitate soil moisture retention, provide nutrients, and maintain soil development and biochemical processes.
- FW-DC-SOIL-03. Volcanic ash-influenced soils are intact and retain unique properties, including high soil porosity and high water and nutrient holding capacity.

These desired conditions emphasize the important role soils have in promoting a resilient and diverse ecosystem that supports ecological integrity as well as addressing the requirements of the 2012 Planning Rule.

Soil management traditionally involves avoiding risks for soil erosion and physical impairment from machine operations. The action alternatives would carry forward and expand sideboards that mitigate impacts. Proposed standards and guidelines were developed to limit impacts on sensitive soils, reduce the amount of new soil disturbance, increase the amount of restoration of impaired soils, and provide thresholds for ground cover and coarse wood material. Through standard FW-STD-SOIL-03, project specific best management practices and design features shall be incorporated into land management activities as a principal mechanism for protecting soil resources. The proposed desired conditions, standards, and guidelines are common to all action alternatives. The soil resource plan components do not apply to intensively developed sites, such as mines, developed recreation sites, administrative sites, rock quarries, trails, or system roads (U.S. Department of Agriculture 2014o).

Soil productivity and function

Timber harvest and associated actions such as temporary road, skid trail, and landing construction would continue as the management activity that produces the highest amount and level of ground disturbance over the next planning period. Most of the timber harvest would occur on lands designated as suitable for timber production in the Land Management Plan. These activities occur primarily in Management Area 3 and small portions of Management Area 2. The exact location of future timber harvest will depend on road access and site-specific forest conditions. However, uncertain disturbance events, such as insect and disease outbreaks or wildfire, would also influence location and extent of harvest.

The Nez Perce-Clearwater proposes that all land management activities be designed and implemented in a manner that maintains soil function and productivity (FW-STD-SOIL-01). The Plan focuses on outcomes to achieve this standard through a mix of mitigation that includes avoidance, logging systems design, retaining sufficient organic matter and coarse wood on the soil surface, and actively reclaiming past and current impaired soils on skid trails, log landings, and temporary roads.

In absence of numerical standards, Appendix 4 - Management Approaches and Possible Actions outlines methods to assess compliance, including but not limited to the use of the numerical thresholds and definitions provided in Northern Region Supplement FSM 2500-2014-1. Appendix 4 also outlines qualitative measures to better assess recovery of soil function from restoration actions. These analysis measures provide a means to quantify the combined effects of limiting disturbance with active restoration.

Damage to soils would be limited by:

- Using existing disturbed areas where practical (MA2 & MA3-GDL-SOIL-02), which would be restored after use.
- Treating areas of impaired soil function from past management activities to restore long-term soil productivity and function (MA2 & MA3-GDL-SOIL-03).
- Decommissioning temporary roads to restore soil function (MA2 & MA3-GDL-SOIL-05).

- Rehabilitating soil function created through future management activities to maintain long-term soil productivity (FW-STD-SOIL-02).

With the emphasis on restoring soil disturbance at a site, the strategy could reinforce best practices through operators that improve post-harvest results. Forest monitoring and reports show that conditions after timber harvest and fuels reduction can weigh heaviest on operator skill (Page-Dumroese et al. 2010). Furthermore, the Nez Perce-Clearwater's use of restoration measures has evolved over 25 years of decommissioning roads. The Nez Perce-Clearwater's proven restoration practices, together with the encouragement of operator best practices, could increase soil recovery rates, restoring vital soil functions to their inherent range of variability. For example, decompacting soils, removing ruts, recontouring slopes, and adding organic matter can reestablish soil functions, including soil biology, soil hydrology, nutrient cycling, carbon storage, soil stability and support, and filtering and buffering.

Although not currently a forest plan standard, the Nez Perce-Clearwater has limited ground-based harvest systems to slopes less than 35 percent unless exempted by a soil scientist. Over the last 20 years, ever improving timber sale contract provisions and best management practices have been developed to minimize the impacts from ground-based harvest systems. Concurrently, advances in machine technology have led to the creation of equipment that is less ground disturbing. Tracked machines have lower ground pressures than wheeled machines and self-leveling cabs shift the overall center of gravity, thereby improving weight distribution over the track (Cambi et al. 2015, Visser and Stampfer 2015). Given similar soil and environmental conditions, activities accomplished with modern tracked machinery are expected to cause less extensive and intense soil disturbance than those accomplished with traditional wheeled machinery.

Using limitations like those described in the Idaho Forest Practices Act best management practices handbook (University of Idaho Extension Office 2015), the Nez Perce-Clearwater proposes guideline MA2 and MA3-GDL-SOIL-01, which includes the following:

- Ground-based equipment used for vegetation management should only operate on slopes less than 45 percent to protect soil quality.
- Log skidding equipment should only operate on slopes less than 35 percent to limit detrimental soil disturbance.
- Exceptions can be authorized where soil, slope, and equipment are determined appropriate to maintain soil functions.

Despite these environmental controls, harvest actions could still leave levels of detrimental soil disturbance. To initiate recovery of impaired soils created from timber harvest, the Nez Perce-Clearwater proposes active restoration of newly created impaired soils on 555 to 2,100 acres annually (FW-STD-SOIL-02) and 75 to 280 acres of soils impaired from past management activities (FW-OBJ-SOIL-01, MA2 and MA3-GDL-SOIL-03), depending on alternative. This soil restoration would occur either within or adjacent to timber harvest units. Calculations assumed a 15 percent creation and restoration of detrimental soil disturbance for every acre of timber harvest proposed. Estimated soil restoration acres of soils impaired from past management activities were calculated using a 2 percent factor for every acre of timber harvest proposed. Actual restoration acres would depend on the timber harvest area, the extent of existing soil disturbance, and the degree harvest activities impair soils. Other soil improvements would be achieved through FW-OBJ-WTR-05 and FW-OBJ-RMZ-01. The No Action Alternative does not have this level of soil restoration integrated in the timber harvest program, allowing for approximately 15 acres of impaired soil to be left on the landscape for every 100 acres of harvest.

The Nez Perce-Clearwater restoration strategy would address legacy impacts from past forest management when conducting forest treatments. Future management activities are expected to re-enter previously harvested stands in their second rotation. Old yarding templates and landing areas not used by current timber sales would be reclaimed as part of a net improvement approach. This strategy follows current policy in the Northern Region Supplement FSM 2500-2014-1 (U.S. Department of Agriculture 2014o) to have management actions leave the soil with an increased rate of recovery upon completion of the activities where existing conditions exceed 15 percent detrimental soil disturbance.

The action alternatives all incorporate thresholds for managing organic matter and maintaining sufficient groundcover to control erosion. Currently, analysis relies on published findings for managing forest residues such as down wood, slash, and forest floor. Forest management and public use activities often disturb or remove ground cover and organic material. This condition allows for erosion where soils are friable or where storm flows can concentrate. Although overland flow and surface erosion are rare in Rocky Mountain forests (Wondzell and King 2003), evaluation of Nez Perce-Clearwater soil data shows most of the plan area has soils easily eroded if ground cover or the forest floor is removed on steep or compacted surfaces. Cover is important since vegetation and forest litter intercept rainfall and slow runoff to allow rainfall to infiltrate into the soil. As determined through use of Disturbed WEPP, a soil erosion model amended for forested environments, soil erosion rarely occurs if groundcover exceeds 85 percent cover (Elliot et al. 1999). Guideline FW-GDL-SOIL-02 establishes a post-implementation ground cover target of 85 percent aerial extent to retain soil moisture, support soil development, provide nutrients, and reduce soil erosion. Ground cover consists of vegetation, litter, fine organic matter, coarse woody material, and rock fragments larger than three-fourths inch in diameter in contact with the soil surface. Guideline FW-GDL-SOIL-02 allows for differential depth and distribution of organic matter depending on the local ecological type and fire regime. This also allows for situations when bare mineral soil is warranted for regenerating early species such as Western larch.

The retention of coarse woody debris, which is material greater than 3 inches in diameter, is essential to maintaining soil organic matter, soil productivity, and sustainable forest ecosystems (Graham et al. 1994). Coarse woody material greater than 12 inches in diameter is preferred. It is implied that larger logs would decay into brown cubicle rot and have proportionally larger contributions to soil wood. In early work by Harvey et al.(1987), almost 57 percent of the ecto-mycorrhizae distribution in this soil wood was derived from downed logs. Guideline MA2 and MA3-GDL-FOR-01 outlines ranges of coarse wood material levels that should be maintained or restored by potential vegetation type. Ranges vary from 7 to 15 tons per acre in warm dry forests to as much as 17 to 33 tons in warm moist forests. It is recognized that management of organic matter for soil function and productivity can conflict with fuel hazard objectives. The coarse wood ranges identified in guideline MA2 and MA3-GDL-FOR-01 fall within the optimum ranges prescribed by Brown et al. (2003) to balance fuels and soils needs.

The continued trend of increased wildfire frequency, along with more emphasis on prescribed burning for restorative purposes, is expected. Future fires may burn through recovering areas that experienced moderate or severe wildfire. Burning through past fire areas that have “jackstrawed” dead trees could produce heat that penetrates deeper into the soil because of longer burn durations. There is concern that this heating can sterilize soils and impede forest growth. Research has shown that despite this heating, reburn rarely sterilizes soil; rather, recovery is controlled by fire severity, tree overstory level, soil texture, and the timing of the burn (Neary et al. 1999, Hebel et al. 2009, Smith et al. 2017). Fire re-organizes the soil community where generalist species dominate early on (Egerton-Warburton et al. 2005, Jiménez Esquilín et al. 2008, Reazin et al. 2016). With time, the soil microbe community evolves in complexity and the soil condition improves as vegetation recolonizes the site and organic matter stocks rebuild.

With projected increased wildfire, fire suppression activities could impact soils from the creation of mechanical fire lines and excavation of safety zones. Fire suppression rehabilitation measures can improve soil and vegetation recovery. The Nez Perce-Clearwater Land Management Plan addresses this critical rehabilitation period by including fire suppression activities in standard FW-STD-SOIL-02, which directs re-establishment of soil function according to site potential. See the management approaches in Appendix 4 of the Land Management Plan.

Protection of sensitive soils

The Land Management Plan would address sensitive soils at the project level through a combination of avoidance and mitigation, depending on the circumstance. The protections rely on soil expertise and incorporation of design measures and best management practices as required by FW-STD-SOIL-03. However, two primary soil types stand out to an extent that the Nez Perce-Clearwater proposes sideboards for management. The first case is for mass movement areas while the second is for conducting salvage timber harvest after wildfire.

The Nez Perce-Clearwater contains over 800,000 acres of lands prone to mass movement. In order to reduce the likelihood of management activities originating from mass movement, the Nez Perce-Clearwater proposes guideline FW-GDL-SOIL-01 – to maintain soil stability, ground-disturbing management activities should not occur on field verified mass movement areas. Vegetation management activities may be authorized to provide long-term slope stability.

The avoidance strategy for active management in mass movement areas comes with some caveats. Avoidance of lands with mass movement potential could lead to higher rates of instability in the long-term when factoring in fire potential. Fire exclusion has created dense vegetation that is departed from natural conditions. Future fire could burn with increased severity that could increase the mass movement potential. For example, in Ponderosa pine stands that are adapted to frequent low-intensity fire, the fire exclusion and restrictions of timber harvest on potential mass movement slopes have resulted in stands highly departed from natural conditions. Legacy trees that survived historic fires and provided slope stability are now overcrowded by fire intolerant species. Further, without frequent fire, forest floor layers are deeper than normal and tree roots have grown up into these layers.

Once a wildfire burns through these stands, there is a high likelihood that most of the trees would not survive, resulting in a higher risk for mass movement due to loss of live tree rooting. Thinning of trees in Ponderosa pine stands and initiating low to mixed severity underburns could make the stand more resilient to wildfire and provide slope stability in the long-term. Appendix 4 of the Land Management Plan includes management approaches and potential design measures that could be used for vegetation treatments in areas with high mass movement potential.

The Nez Perce-Clearwater also acknowledges the risks associated with road and trail construction on landslide prone areas. To address this risk, the Nez Perce-Clearwater proposes guidelines that limit the construction of new and relocated roads and trails on lands with high mass movement potential (FW-GDL-ARINF-04 and FW-GDL-ARREC-04) and a guideline that provides direction on routing road drainage away from potentially unstable hillslopes (FW-GDL-ARINF-09).

Salvage harvest operations that occur after wildfire have the potential to detrimentally disturb soils and cause long-term impairment. Because salvage harvest occurs on soils that have already been impacted by wildfire, soils are less resilient to additional impacts from ground disturbance. This is especially true in areas where soils were severely burned, altering the soil chemical, biological, and physical properties. To protect these soils, the Nez Perce-Clearwater proposes to maintain long-term soil productivity when conducting post-wildfire vegetation management activities by avoiding permanent soil impairment on soils that have verified high soil burn severity (MA2 and MA3-GDL-SOIL-04). Permanent soil impairment is defined as the detrimental changes in soil properties (physical, chemical, and biological) that result in the loss of the inherent ecological capacity or hydrologic function of the soil resource that lasts beyond a land management planning period.

Cumulative Effects

Past actions and foreseeable future actions primarily affect soils at the site location. Influence from adjacent management on private, state, or federally managed areas would have undetectable effects on site-specific soil conditions. Legacy disturbance from past and present management actions could affect the soil condition where future management activities are planned.

Effects to Soil Resource from Other Resources

Fire Management

The fire management program is diverse and impacts soils differentially. Fire effects related to prescribed fires, fuels treatments, and fire suppression operations are discussed in this section. Fire effects from site preparation after harvest activities is discussed in the Effects to Soil Resource from Timber Harvest section.

Prescribed Fire

The Nez Perce-Clearwater is characterized as fire-adapted or fire-dependent and, thus, requires periodic fire to maintain healthy, resilient conditions. Within these ecosystems, prescribed fire can help restore and sustain long-term environmental health. A prescribed fire is a planned fire intentionally ignited by fire specialists to meet management objectives. Natural fuels prescribed fire is analyzed differently than activity fuels burning for site preparation after timber harvest. Natural fuels prescribed fires are conducted at a larger scale and are used to reintroduce or maintain fire disturbance within the landscape scale natural fire regime and to meet a variety of vegetation, wildlife, and watershed desired conditions. Fire managers develop site specific burn plans that consider many factors, such as weather conditions and expected fire effects. Prescribed fires generally result in lessened fire effects than wildfire occurring under extreme weather and fuel moisture conditions.

Effects to soils from prescribed fire may be similar to wildfire. Effects would vary depending on the management objective. Underburning in drier potential vegetation types results in low and moderate burn severity that retains much of the soil ground cover. A mixed burn severity prescription in more moist potential vegetation types could lead to increased soil erosion from loss of ground cover in areas of moderate to high burn severity, although recovery generally occurs in one to three years, depending on remaining ground cover. This post-burn condition is highly variable spatially and decreases over time (Doerr et al. 2006).

Prescribed fire would promote the re-establishment of fire-adapted ecological processes. Fire can improve soil condition by creating a net increase in available nutrients, both in terms of ash residue and the higher decomposition rates after the fire. Burning increases the amount of mineral nitrogen levels for plants and soil organisms (Choromanska and DeLuca 2002, Hart et al. 2005), which is a limiting nutrient in most forest ecosystems (Binkley 1991). In drier habitats, this increase can be detected as much as 50 years after fire occurrence (McKenzie et al. 2004). Burning also increases charcoal production that conditions soils, increasing water-holding capacity and providing exchange sites for plants and soils to acquire nutrients (DeLuca and Aplet 2008).

Although there is a potential for temporary loss of ground cover and soil erosion, the effects are within the natural range of variation. The reintroduction of wildland fire provides more beneficial effects to the soil resource than negative effects.

Fuels Management

The Nez Perce-Clearwater would continue to treat fuels using a combination of mechanical thinning or masticating; machine piling and burning; hand thinning, piling, and burning; hand thinning and chipping; and underburning. The effects to soils from the use of ground based mechanized equipment can cause varying degrees of removal or modification of vegetative cover and surface organic material; removal or modification of topsoil or volcanic ash layer through soil erosion, displacement, compaction, rutting, or mixing; or exposure or mixing of subsoil. Depending on the degree of disturbance, soil quality, function, and productivity can be impaired. Burning of piles can impact soils through long duration heating at the center of the piles. These impacts can be severe enough to alter soil structure and reduce nutrients to the extent where soils and vegetation recover very slowly over time. The effect can be moderated by creating smaller piles and burning during cooler conditions.

Acknowledging that fuels treatment often requires the use of ground-based mechanical equipment and that impacts to the soil resource would be similar to those discussed in the Timber section, the same plan components would apply. See Effects to Soil Resource from Timber Harvest analysis below.

Forestlands guideline MA2 and MA3-GDL-FOR-01, specifying a minimum retention level of coarse wood material, can often conflict with the intent of fuel treatments. By maintaining coarse wood at the lower end of the range and leaving larger diameter materials, both components can be met. The intent is to create a condition that prioritizes public safety, promotes forest resilience to wildfire, and still allows for functioning ecological processes.

Another guideline regarding retaining a minimum level of soil organic matter and groundcover (FW-GDL-SOIL-02) can also conflict with the desire for reduced ground fuels. The loss of vegetation due to treating fuels is not far removed from natural processes since fire regularly removes vegetation by volatizing biomass. However, the impact may vary by site type. Areas with dense organic matter in the topsoil and that grow abundant grasses and forbs on dry sites likely experienced frequent fire. In these areas, treating fuels aligns with ecological processes and the soils have a higher proportional amount of organic matter in the mineral soils to buffer the removal of vegetation. Underburning to maintain the benefits of fuels treatment in drier habitats would have minimal impact and in some cases be beneficial.

Fire Suppression Operations

Wildland fire management consists of actions based on safety, economics, social considerations, and anticipated environmental effects. When a wildfire occurs, the first priority is the protection of human life and the safety of the public and firefighters. All alternatives would have similar direction for fire suppression operations and thus similar effects. Management strategies and methods vary depending on which management area a wildfire occurs. Wildfires occurring in locations within Management Area 1 and Management Area 2 may be managed to achieve land management plan objectives with minimal active suppression actions. In locations within Management Area 3, more active fire suppression methods are used.

Since it is nearly impossible to predict the extent and location of future wildfires, quantifying the effects to the soil resource is difficult. Wildfire suppression in Management Area 3 lands would have greater impacts than on Management Area 1 and Management Area 2 lands, as more ground disturbing methods are used. Fire suppression operations, such as the construction of machine fire lines and establishment of large fuel breaks, can cause loss of ground cover, soil compaction, rutting, or mixing of topsoil.

Depending on the extent of ground disturbance, soil erosion could occur, and soil functions could be impaired. In some instances, the creation of fuel breaks can cause equal or greater impact to soil resources than timber harvest activities. In emergency situations, equipment is used on steeper slopes than generally occurs during timber harvest operations and equipment operators may be less experienced.

Proposed Land Management Plan component FW-STD-SOIL-02 would mitigate the disturbance created by fire suppression operations. To maintain long-term soil productivity, impaired soil function created through management activities, including fire suppression, shall be rehabilitated to reestablish soil function to the appropriate site potential.

Infrastructure

Intensively developed sites such as mines, developed recreation sites, administrative sites, rock quarries, and trails or system roads (U.S. Department of Agriculture 2014o) are not considered part of the productive land base as soil quality and function are impaired. Although not evaluated for effects to soil productivity, roads can impact sensitive soils, increasing surface and subsurface soil erosion and contributing to mass failures.

The Nez Perce-Clearwater would continue to reduce the National Forest System lands road system to the levels established in current and future travel plans (Bergstrom 2018). Future road building would likely be confined to realignment or relocation, although new roads could be constructed to reach currently inaccessible areas. The road system, including miles, management level, and location, is the same for all alternatives; however, road use would vary by alternative.

Proposed guidelines limit the construction of new and relocated roads and trails on lands with high mass wasting potential (FW-GDL-ARINF-04) and riparian and wetland areas where hydric soils occur (FW-GDL-ARINF-08). Guideline FW-GDL-ARINF-09 provides direction on routing road drainage away from potentially unstable hillslopes. Guideline MA2 and MA3-GDL-SOIL-05 directs that when roads are decommissioned, soil function appropriate to site potential shall be restored using demonstrably effective methods. Appendix 4 of the Land Management Plan outlines well established methods for road decommissioning.

To reduce erosion and potential road prism failures, a series of road treatments are proposed. They include road maintenance (FW-OBJ-INF-02), road reconstruction and improvement (FW-OBJ-INF-01), and road stormproofing (FW-OBJ-CWN-02). The proposed miles of treatment vary by alternative and correspond with the estimated level of increased road use.

Invasive Species Management

The introduction and expansion of a wide range of invasive species has important impacts on soil processes, which are exacerbated by climatic changes. Invasive species lead to a decline of biodiversity and changes in organic matter composition and nutrients. Problematic species can create soil conditions that enhance flash flooding, soil erosion, and sediment loading (Pouyat et al. 2020). The proposed desired condition for invasive species is that invasive species either are not present or occur at low levels to allow watersheds, vegetation communities, and aquatic ecosystems to retain their inherent resilience and resistance to respond and adjust to disturbances. Plant communities retain their historic diversity and provision of values to fauna (FW-DC-INV-01).

Invasive plants are often treated using an integrated approach with a combination of control types that include manual, biological, cultural, and chemical methods. Manual treatment, which is essentially hand pulling, can result in localized soil disturbance as plants are removed. It is very labor intensive and costly;

thus, only a small number of acres per year could be treated using this technique. There are no effects to the soil resource from biological control methods, as there is no disturbance of ground cover or soil. Cultural methods generally involve enhancing the desirable vegetation to minimize invasive plant invasion. Planting or seeding desirable species to shade or out-compete invasive plants are common cultural treatments.

Effects from herbicide application depend on the type, extent, and amount of herbicide that is used. Chemical persistence in the soil profile depends on the soil texture, infiltration rate, chemical half-life, local climate, and the size of the treatment area. Effects of herbicide treatment to the soil resource would be localized. Applications would occur at the appropriate time of year, considering targeted species and environmental factors. Adverse impacts to soils are controlled through limits on herbicide type and application rates outlined in various National Environmental Policy Act documents.

Livestock Grazing

Soil trampling and trailing can cause soil compaction and loss of vegetation cover, which reduces soil function. Soil disturbance increases susceptibility to invasive species. Combined with the fact that livestock are transporters of invasive plant seed, invasive species could exponentially spread across allotments and surrounding areas. Salting sites are particularly disturbed due to the loss of vegetative cover, organic material, and topsoil. Salt leaching can contaminate the soil, making it difficult for vegetation to reestablish.

The Land Management Plan's soil desired conditions and the soil standards and guidelines apply to livestock grazing in addition to vegetation management activities, such as timber harvesting and fuels treatments. These standards ensure that soil function and productivity are maintained long term (FW-STD-SOIL-01 and FW-STD-SOIL-02). The management approach for Soil productivity and function in Appendix 4 of the Land Management Plan reference the methods most applicable to determining effects to the soil resource. These include biologic integrity, soil stability, and hydrologic function, which are the main groups of indicators used in the multi-agency technical reference Interpreting Indicators of Rangeland Health (Pellant et al. 2020) compiled by the Bureau of Land Management. The Land Management Plan states that best management practices would be developed at the project level (FW-STD-SOIL-03), which, in the case of livestock grazing, best management practices would be incorporated in the allotment management plans and annual operating instructions.

Impacts to the soil resource from livestock grazing are localized but tend to be highest near riparian and wetland areas, which contain sensitive hydric soils. Proposed standards and guidelines FW-GDL-GRZ-01, FW-STD-ARGRZ-01, FW-STD-ARGRZ-02, FW-GLD-ARGRZ-01, and FW-GLD-ARGRZ-03 require monitoring and adjustment of grazing practices as necessary to promote healthy riparian and wetland ecosystems.

Specific allotment management plans and annual operating instructions provide instructions to grazing permittees designed to ensure adequate riparian and upland resource protection while providing for the sustainability of forage. These plans, and the direction they contain, are site specific for each allotment and not part of this analysis. Allotment management plans identify specific management actions required by the permittee and may include entry and exit dates; pasture rotation; utilization standards; range improvement construction, reconstruction, and maintenance; salt placement; closed areas; and required monitoring.

Sustainable Recreation

Intensively developed sites, such as developed recreation sites and trails, are not considered part of the productive land base, as soil quality and function are impaired. Dispersed recreation and off-road vehicle use associated with dispersed sites can negatively impact the soil resource. The Clearwater National Forest travel plan allows for off-road travel to dispersed sites for 300 feet off National Forest System roads. The Nez Perce National Forest travel plan allows for off-road motorized travel in certain areas.

If infrastructure is insufficient for developed recreation, then recreational use may shift to dispersed recreation sites. The result of this could be additional and unregulated deleterious effects on the soil resource. Dispersed camping and day use could remove ground cover and topsoil. Down woody material could be removed for firewood use. Impacts from user-created trails to and within the dispersed area may include rutting, erosion, and loss of ground cover from trampling of vegetation, vegetation removal, and soil compaction. These disturbances reduce overall soil quality, function, and productivity. Recreational use is expected to increase in all alternatives, and with the increased use, impacts would be expected to increase. These impacts are localized and occur on less than 1 percent of the Nez Perce-Clearwater.

Timber Harvest

Timber harvest and associated actions would continue as the management activity that produces the highest amount and level of ground disturbance over the next planning period. Timber harvest and associated actions include temporary road, skid trail, and landing construction; general heavy equipment operations; and site preparation. The exact location of future timber harvest would depend largely on factors related to road access and site-specific forest conditions relative to the integrated desired conditions as outlined in the Land Management Plan. However, uncertain disturbance events, such as insect and disease outbreaks or wildfire, could also influence location and extent of harvest.

Timber harvest requires the use of machinery that can compact and displace soils (Cambi et al. 2015, Page-Dumroese et al. 2010). Timber harvest and associated actions can remove or modify ground cover and surface organic material; remove or modify topsoil or the volcanic ash layer through soil erosion, displacement, compaction, rutting, mixing, or severe burning; expose a mixed subsoil; and increase mass movement potential. These disturbances can lead to a loss of soil quality, function, and productivity. This is especially concerning when soil impairment occurs on sensitive soils, including grussic soils, soils with a volcanic ash layer, and soils with a high erosion or mass movement potential.

The intensity and extent of impacts are managed by timber sale contract provisions and best management practices. The Forest Service evaluates the effectiveness of national forest best management practices by comparing disturbance extent against soil quality thresholds. When soil disturbance surpasses these thresholds, then long-term impairment could occur and the disturbance is considered detrimental to soil quality (U.S. Department of Agriculture 2014o). Forest monitoring on the Nez Perce-Clearwater has shown that the highest soil disturbance occurs when using ground-based harvesting and skidding methods. Within an activity area, typically defined as a treatment unit, timber harvest over the next planning cycle would likely impact soils at the same disturbance intensity as over the last 15 years. Nez Perce-Clearwater soil monitoring over this period found that logging systems result in detrimental soil disturbance on a percent area basis of 8 to 29 percent for ground-based harvest systems, one to 10 percent for skyline, and less than 2 percent for helicopter yarding (Archer 2008, Reeves 2011, Bergstrom 2018).

Although timber harvest and associated actions produce the highest amount and level of ground disturbance, implementing forestlands objectives to trend towards vegetative desired conditions would result in a more resilient landscape with a higher adaptive capacity. The plan components in the forestlands section were developed to maintain or restore the composition, structure, function, and connectivity of terrestrial ecosystems that better match natural fire regimes, considering multiple spatial and temporal scales.

Timber Harvest Operations

Soil disturbance during timber harvest cannot be avoided, but it can be managed. The Nez Perce-Clearwater proposes that land management activities shall be designed and implemented in a manner that maintains soil function and productivity (FW-STD-SOIL-01) and that timber shall not be harvested on lands where soil, slope, or other watershed conditions would be irreversibly damaged, as identified in project-specific findings (FW-STD-TBR-03). Proposed standard FW-STD-SOIL-03 requires project specific best management practices and design features shall be incorporated into land management activities as a principal mechanism for protecting soil resources.

All detrimental soil disturbance areas would be targeted for soil restoration, regardless of the cause. This would be accomplished by limiting new soil disturbance through use of existing disturbed areas (MA2 & MA3-GDL-SOIL-02), which would be restored after use; treating areas of impaired soil function from past management activities in order to restore long-term soil productivity and function (MA2 & MA3-GDL-SOIL-03); decommissioning temporary roads to restore soil function (MA2 & MA3-GDL-SOIL-05); and rehabilitating impaired soil function created through future management activities in order to maintain long-term soil productivity (FW-STD-SOIL-02). These practices increase soil recovery rates by restoring vital soil functions to their inherent range of variability.

The Nez Perce-Clearwater proposes active restoration of newly created impaired soils on 555 to 2,100 acres annually (FW-STD-SOIL-02) and 75 to 280 acres of soils impaired from past management activities (FW-OBJ-SOIL-01, MA2 and MA3-GDL-SOIL-03), depending on alternative. These acres would occur primarily within or adjacent to timber harvest units. Actual restoration acres would be dependent on the amount of timber harvest implemented, the extent of existing soil disturbance, and the amount of soil impairment created through the harvest activity. Other soil improvements could be achieved through FW-OBJ-WTR-05 and FW-OBJ-RMZ-01.

The Nez Perce-Clearwater's reduction in miles of National Forest System roads has increased the reliance on temporary roads to access timber. The greatest disturbance associated with the activities is the displacement or mixing of the topsoil, including the Mazama ash cap, during excavation. Temporary roads, excavated skid trails, and landings are considered 100 percent detrimental disturbance with reduced soil productivity until elements, such as vegetative cover, organic matter levels, biologic function, and hydrologic function, are restored. Restoration following use would promote a more rapid recovery of soil structure, water infiltration, aeration, root penetrability, and soil biological activity. Demonstrably effective techniques for soil restoration include the well-established methods for road decommissioning that have been developed on the Nez Perce-Clearwater. For example, active recontouring of slopes can dramatically accelerate the recovery of soil properties, while belowground properties and processes along abandoned roads remain in a degraded state even 30 or more years after road closure and revegetation (Lloyd et al. 2013).

A recent shift in timber practices that may increase soil disturbance over the next planning period includes the use of cable assisted logging, which is a mixed ground-based and skyline system on grounds with greater than 45 percent slope. In these steep areas, cable-assisted feller bunchers harvest the trees and skyline systems yard the material to landings. Monitoring has shown mixed results ranging below and above what is typical of ground-based equipment operations. In March of 2022, the Idaho Forest Practices Act was updated. Rules specific to the use of ground-based equipment on steep slopes were updated due to technological changes in the industry which allow machinery to operate safely on steep slopes while minimizing soil disturbance (Idaho Department of Lands 2022b).

Site Preparation

Methods for reducing slash material after timber harvest include machine piling and burning or broadcast burning. Machine piling equipment can create additional ground disturbance if the equipment leaves designated skid trails. Impaired soil conditions within burn pile scars can persist for several decades due to concentrated heating (Jiménez Esquilín et al. 2008, Rhoades and Fornwalt 2015). The effect can be moderated by creating smaller piles and burning during cooler conditions.

Broadcast burning removes slash and understory vegetation to facilitate reforestation but has had negative consequences by consuming the forest floor and leaving scant groundcover. It is also used in conjunction with whole tree yarding that removes fuel even before burning.

Depending on slope, vegetation type, slash amounts, and tree retention levels, broadcast burns can produce a varying range of soil burn severities. Moderate to high severity burns consume most of the ground cover, smaller diameter down wood, and sometimes tree boles and roots. Fires that heat soils to high temperatures can volatilize organics and produce a hydrophobic layer that contributes to higher rates of runoff and more soil erosion.

Current findings from the Forest Service's long-term soil productivity study suggest that the extent of negative impacts from vegetation management activities is related to soil texture and organic matter (Page-Dumroese et al. 2010, Powers et al. 2005) but often as conflicting variables. For example, coarse-textured soils appear resistant to compaction (Gomez et al. 2002) but are also nutrient poor and particularly at risk to treatments that remove the forest floor (Page-Dumroese et al. 2010, Page-Dumroese and Jurgensen 2006). Forestry research has underscored the importance of organic matter by documenting the soil benefits of downed wood (Graham et al. 1994, Harvey et al. 1987), forest floor, and soil organic matter (Jurgensen et al. 1997). However, at this time the Nez Perce-Clearwater has no clear guidance on target levels by habitat or soil type since organic matter levels vary in step with forest succession. The Rocky Mountain Research Station has initiated studies to establish minimal necessary amounts of organic matter by habitat type. In the interim, the following proposed guidelines are used to conserve the forest floor and coarse wood levels:

FW-GDL-SOIL-02. Project activities should provide sufficient effective ground cover, such as litter, fine and coarse wood material, or vegetation with a post-implementation target of 85 percent aerial extent of an activity area to retain soil moisture, support soil development, provide nutrients, and reduce soil erosion. The depth and distribution of organic matter should reflect the amounts that occur for the local ecological type and natural fire regime.

MA2 and MA3-GDL-FOR-01. To ensure sufficient organic materials to maintain nutrient cycling and soil biology and to provide habitat structure for various terrestrial wildlife, the levels listed in Table 112 of downed coarse woody material greater than 3 inches should be retained onsite following regeneration harvest and fuels management and site preparation activities. Coarse woody material greater than 12 inches in diameter is preferred. The following amounts are recommended by Graham et al (1994) and are intended to give general direction for retention of coarse woody debris within potential vegetation type groups. If sufficient downed coarse woody material is unavailable, standing retained trees and snags may be counted toward meeting the numbers in the table below. Exceptions to vary from the ranges listed may occur in areas near administrative sites, developed recreation sites, sensitive natural resources, or historic properties. Coarse woody material should be well distributed across each treatment unit.

Table 112. Coarse woody materials to maintain by potential vegetation type (PVT) group.

PVT Group	Tons per Acre
Warm Dry	7–15

PVT Group	Tons per Acre
Warm Moist	17–33
Cool Moist	9–18
Cold	7–24

Salvage Harvest after Wildland Fire

Salvage harvest is a type of timber harvest that could occur after wildfire. The intent is to harvest dead and dying trees to recover the existing economic value or to remove hazard trees for safety purposes. Salvage harvest is addressed specifically because of potential for long-term soil impairment of soils with high burn severity. Because salvage harvest occurs on soils that have already been impacted by wildfire, soils are less resilient to additional impacts from ground disturbance. This is especially true in areas where soils were severely burned, which alters the soil chemical, biological, and physical properties. Generally, the commercial value of trees is lost in areas that have severely burned so salvage harvest is not pursued where these occur in larger areas. Issues arise in areas where there is a mosaic of moderate and high burn severity and there is a commercial component left in the moderately burned areas.

The classification of post-fire soil condition is based on fire-induced changes in physical and biological soil properties. During post-fire assessments, there has been an intentional effort to use the term "soil burn severity" to differentiate post-fire soil properties from fire effects on vegetation, such as tree mortality, and general fire effects on long-term ecosystem health (Parsons et al. 2010).

The following description for high soil burn severity is taken from Debano et al. (1998), pages 62 and 63:

"High soil heating, or deep ground char, occurs where the duff is completely consumed, and the top of the mineral soils is visibly reddish or orange on severely burned sites. The char layer can extend to a depth of 10 cm or more. Logs can be consumed, or deeply charred and deep ground char can occur under burned logs. Soil textures in the surface layers are changed and fusion evidenced by clinkers can be observed locally. All shrub stems are consumed and only the charred remains of large stubs may be visible."

To protect these soils, the Nez Perce-Clearwater proposes that, when conducting post wildfire vegetation management activities, to maintain long-term soil productivity, avoid permanent soil impairment on soils that have verified high soil burn severity (MA2 and MA3-GDL-SOIL-04). Further, guidelines FW-GDL-SOIL-02, MA2-GDL-FOR-01, and MA3-GDL-FOR-01 require maintenance of ground cover and coarse woody material. Additionally, project specific best management practices and design features shall be incorporated into land management activities as a principal mechanism for protecting soil resources (FW-STD-SOIL-03).

Aquatic Ecosystems Management

In addition to the soil restoration objectives proposed in the timber sale activity areas, the Nez Perce-Clearwater proposes 2,500 to 5,300 acres of soil and watershed improvement every 5 years (FW-OBJ-WTR-05), depending on alternative. The preferred alternative proposes to improve soil and watershed conditions on 3,000 to 4,000 acres every 5 years (FW-OBJ-WTR-05). Soil improvement activities on existing disturbed areas are expected to accelerate soil recovery and result in immediate or near-term improvement within approximately one to five years. These improvement activities would also provide support for continued long-term recovery of soil functions and productivity.

Irreversible and Irretrievable Commitments of Resources

The National Forest Management Act states that Land Management Plans must ensure timber harvest does not occur where soils will be irreversibly damaged. The analysis addressed this risk by extracting high risk areas for soil loss from suitable timber harvest areas. The soil plan components further address soil risks by providing standards and guidelines. The soils analysis above identifies and discusses sensitive soils for project planning efforts to consider for soil loss hazards to avoid leading to irreversible damage.

The National Environmental Protection Act Council of Environmental Quality regulations require the Forest Service to identify when making an irreversible and irreplaceable commitment. Since this Land Management Plan decision is not authorizing or committing to any action, the Land Management Plan cannot make any irreversible and irretrievable commitments. The Nez Perce-Clearwater would only consider these commitments on a project basis.

Summary of Consequences

The alternatives were compared using proposed timber harvest objectives and the estimated proportional soil restoration associated with the activity (Table 113). Calculations assumed a 15 percent creation and restoration of detrimental soil disturbance for every acre of timber harvest proposed. Estimated soil restoration acres of soils impaired from past management activities were calculated using a 2 percent factor for every acre of timber harvest proposed. Actual restoration acres would be dependent on the amount of timber harvest implemented, the extent of existing soil disturbance, and the amount of soil impairment created through the harvest activity.

Table 113. Summary of soil productivity and function indicators by alternative.

Measurement Indicator	No Action	Alternative W	Alternative X	Alternative Y	Alternative Z	Preferred Alternative
Timber harvest acres annually	3,800	12,600	14,000	7,500	3,700	8,825–10,000
Estimated annual acres[1] soil restoration of detrimental soil disturbance to comply with plan component FW-STD-SOIL-02	0	1,890	2,100	1,125	555	1,325–1,500
Estimated annual acres[2] soil restoration of soils impaired from past management activities within or adjacent to harvest units to implement objective FW-OBJ-SOIL-01 and comply with plan component MA2 and MA3-GDL-SOIL-03	0	250	280	150	75	175–200

[1]Actual restoration acres would be dependent on the amount of timber harvest implemented, the extent of existing soil disturbance, and the amount of soil impairment created through the harvest activity.

[2]Actual restoration acres would be dependent on the extent of existing soil disturbance.

Conclusion

To maintain and, where necessary, restore long-term soil quality, function, and productivity, it is important that activities causing impairment to the soil resource be managed within acceptable limits. Land-use national forest practices have affected soil functions, and these functions are intertwined, making it difficult to discuss them separately. This Land Management Plan would increase the number of environmental screens to mitigate adverse soil effects from forestry activities, as well as other management actions. Flexibility is extended to slope limits if soil desired conditions and standards are met. The new plan also expands direction by not only adding levels of protection through avoidance and minimization but by promoting active restoration to maintain long-term soil productivity. The current forest plan standards, along with current guidance at the Regional and Washington Office level, interpret the National Forest Management Act's direction for soils to manage for sustained soil productivity. The proposed Land Management Plan would continue to manage for long-term soil productivity as described in desired condition FW-DC-SOIL-01 emphasizing soil productivity and function contributes to the long-term resilience of ecosystems.

The Land Management Plan includes plan components that support the maintenance or restoration of soils and soil productivity, including guidance to reduce soil erosion and sedimentation (36 CFR 219.8(a)(2)(ii)). The plan components emphasize the important role soils have in promoting a resilient and diverse ecosystem that supports ecological integrity.

The following key points summarize the conclusions for the soils resource:

- The action alternatives contain desired conditions, standards, and guidelines that would ensure that soil functions are maintained to a greater extent than the current forest plan. The new Land Management Plan provides consistent soil direction.
- The Land Management Plan brings forward and formulizes minimization and avoidance criteria to limit soil impairment.
- There is added flexibility for ground-based slope steepness to account for advances in harvest equipment.
- The focus on outcomes involves active soil restoration. Added language on the elements of soil function and productivity would allow for better prescriptions. Additionally, there is direction to treat soils with impaired soil function from past management activities to facilitate long-term productivity.
- Adopted conservation measures of groundcover and organic materials after timber harvest, fuels treatments, and prescribed burning would limit erosion while ensuring soil function.

Management strategies that provide for ecological sustainability include mitigating the effects of stressors, maintaining or restoring ecological integrity, or incorporating adaptation strategies to reduce vulnerability. By restoring or maintaining functioning soils, ecosystems would have greater adaptive capacity to withstand stressors and recover from disturbances with minimum loss of function, especially with changing and uncertain environmental conditions and extreme weather events.

3.2.7 Water Resources

The watersheds, rivers, and streams of the Nez Perce-Clearwater provide many ecological, economic, and social benefits. Clean water is a critical resource with over 9,500 miles of perennial streams and 3,800 acres of lakes and ponds supporting high value recreation, municipal water, and habitat for unique and diverse populations of fish and wildlife. Tens of thousands of people rely on water from the national forests for drinking water, recreation, agriculture, industry, hydropower generation, and other uses. The types of water use and increased demand will affect how the Nez Perce-Clearwater manages watershed conditions that influence water quality and quantity for a variety of beneficial uses. Managing for high quality water and properly functioning watershed condition are fundamental for maintaining and restoring watershed health and ecosystem resilience.

The Water Resources section describes the affected environment, and environmental consequences of the alternatives with respect to long-term ecological, social, and economic sustainability related to watersheds and water resources. Water resources that provide ecosystem services or benefits to people and surrounding communities support economic and social sustainability. Resilient and functioning watersheds provide for ecological sustainability.

Changes Between Draft and Final Environmental Impact Statements

Comments received since the publication of the proposed action and Draft Environmental Impact Statement have been used where appropriate to improve the Land Management Plan and have helped inform this Final Environmental Impact Statement. Multiple minor changes were made in the Final Environmental Impact Statement; all changes are within the scope of the Draft Environmental Impact Statement analysis and address issues that the public had an opportunity to comment on. With respect to water resources, there were changes to the Aquatic Ecosystems plan components that were driven from commenters and internal Forest Service recommendations. Also, as a result of public input, an additional alternative was developed. The Preferred Alternative is a compilation of portions of the other alternatives analyzed in detail in the Draft Environmental Impact Statement. Analysis of the Preferred Alternative for water resources is similar to the other action alternatives.

Relevant Laws, Regulations, and Policy

The Nez Perce-Clearwater will follow all laws, regulations, and policies that relate to managing National Forest System land. The Land Management Plan is designed to supplement, not replace, direction from these sources. Other Forest Service direction, including laws, regulations, policies, executive orders, and Forest Service directives (manual and handbook), are not repeated in the Land Management Plan.

Federal Laws

Organic Administration Act of 1897: This act states that one aspect of the mission of the national forests is to "provide favorable conditions of water flow."

Department of Agriculture Organic Act of 1944: This act provides direction on the establishment and protection of water rights.

Federal Water Pollution Control Act (Clean Water Act) of 1948, as amended in 1972, 1977 and 1987: This act was revised by amendments in 1972 that gave the act its current form and spelled out programs for water quality improvements. Direction is intended to restore and maintain the chemical, physical, and biological integrity of the nation's waters. Section 208 of the 1972 amendments mandates identification and control of nonpoint source pollution resulting from silvicultural activities. There are five required elements: 1) Compliance with state and other federal pollution control rules; 2) No degradation of instream water quality needed to support designated uses; 3) Control of nonpoint source water pollution using conservation or "best management practices;" 4) Federal agency leadership in controlling nonpoint sources pollution from managed lands; and 5) Rigorous criteria for controlling discharge of pollutants into the nation's waters. Section 404 establishes a program to regulate the discharge of dredged or fill material into waters of the United States, including wetlands. The 1987 amendments added Section 319 to the act, under which states are required to develop and implement programs to control nonpoint sources of pollution or rainfall runoff from farm and urban areas, as well as construction, forestry, and mining sites. Sections 303 and 305 mandate the listing and reporting of waters not meeting water quality standards that are intended to support beneficial uses of a waterbody. Section 303(d), which requires states to identify pollutant-impaired water segments and develop "total maximum daily loads" that set the maximum amount of pollution that a water body can receive without violating water quality standards.

Multiple-Use Sustained-Yield Act of 1960: Congress has affirmed the application of sustainability to the broad range of resources over which the Forest Service has responsibility. The Multiple-Use Sustained-Yield Act confirms the Forest Service's authority to manage the national forests and grasslands "for outdoor recreation, range, timber, watershed, and wildlife and fish purposes" (16 U.S.C. 528) and does so without limiting the Forest Service's broad discretion in determining the appropriate resource emphasis or levels of use of the lands of each national forest and grassland.

Safe Drinking Water Act of 1974, as amended 1986 and 1996: The goal of the act is to assure a safe supply of drinking water. The 1996 amendment provides states with more resources and authority to enact the Safe Drinking Water Act of 1974. This amendment directs the states to identify source water protection areas for public water supplies that provide water for human consumption and that serve at least 25 people or 15 service connections for at least 60 days a year. These systems can be dependent on any type of water source, including streams, lakes, reservoirs, springs, or wells and include systems used either year-round or only seasonally.

Agricultural Improvement Act of 2018 (a.k.a. the 2018 Farm Bill), Section 8405: permanently authorizes the Forest Service to develop and maintain the Watershed Condition Framework, using the agency's existing processes and criteria.

Under the **Northwest Power Act of 1980** and the **Federal Power Act of 1920, as amended**, federal entities, specifically the Bonneville Power Administration, Federal Energy Regulatory Commission, U.S. Army Corps of Engineers, and the Bureau of Reclamation, must consider Protected Area status and restrictions when making decisions regarding hydroelectric facility permits and access to electricity from those facilities.

Executive Orders

Executive Order 11988 (May 24, 1977), as amended: This order directs federal agencies to take action on federal lands to avoid, to the extent possible, the long- and short-term adverse impacts associated with the occupancy and modification of floodplains. Agencies are required to avoid the direct or indirect support of development on floodplains whenever there are reasonable alternatives and evaluate the potential effects of any proposed action on floodplains.

Executive Order 11990 (May 24, 1977), as amended: This order requires federal agencies exercising statutory authority and leadership over federal lands to avoid, to the extent possible, the long- and short-term adverse impacts associated with the destruction or modification of wetlands. Where practicable, direct or indirect support of new construction in wetlands must be avoided. Federal agencies are required to preserve and enhance the natural and beneficial values of wetlands.

Agency Regulations

36 CFR 219.7: Specifies that during revisions, Land Management Plans must identify watershed(s) that are a priority for maintenance or restoration (36 CFR 219.7(f)(1)(i)). Priority watersheds are identified through the Forest Service Watershed Condition Framework.

36 CFR 219.8: Requires the Chief of the Forest Service to establish requirements for national best management practices for water quality in the Forest Service Directive System (36 CFR 219.8(a)(4)) and stipulates forest plans include plan components to maintain or restore water quality (36 CFR 219.8(a)(2)(iii)), water resources (36 CFR 219.8(a)(2)(iv)), and riparian areas (36 CFR 219.8(a)(3)).

36 CFR 251.9: Authorizes the Chief of the Forest Service to enter into agreements with municipalities to restrict the use of National Forest System lands from which water is derived to protect municipal water supplies.

Policy

Forest Service Manual and Handbook Direction: Forest Service manuals and handbooks within the 2500 file code designation contain direction for watershed management. Forest Service Handbook 2509.22, Soil and Water Conservation Practices (U.S. Department of Agriculture 1988a) contains direction on developing site-specific soil and water conservation practices for use on National Forest System lands in the Northern Region and Intermountain Region to comply with direction in the Clean Water Act.

Other Federal Guidance

National Core Best Management Practices Technical Guide (U.S. Department of Agriculture 2012b) Volume 1 outlines national best practices to improve management of water quality consistent with the federal Clean Water Act and state water quality programs and to integrate water resource protection into management activities conducted across the landscape. Direction for the implementation of this program is found in Forest Service Handbook 2509.19.

Watershed Condition Framework (U.S. Department of Agriculture 2011d). The Framework is a nationally consistent, comparable, and credible process for improving the health of watersheds on national forests and grasslands. It provides the Forest Service with an outcome-based performance measure for documenting improvements to watershed condition at forest, regional, and national scales.

State and Local Laws

Idaho Department of Water Resources

Idaho Stream Channel Protection Act of 1971 (Title 42, Chapter 38, Idaho Code): This act regulates stream channel alterations between mean and high-water marks on perennial streams in Idaho. Instream activities on National Forest System lands must adhere to the rules pertaining to the act (Idaho Administrative Procedures Act [IDAPA] 37.03.07). The act requires an individual or entity to obtain a stream channel alteration permit from the Idaho Department of Water Resources before commencing a streambank or stream channel altering activity.

Idaho Department of Environmental Quality

Ground Water Quality Rule (IDAPA 58.01.11): This policy prevents contamination of ground water from all regulated and nonregulated sources of contamination to the maximum extent practical.

Idaho Rules for Public Drinking Water Systems (IDAPA 58.01.08): This rule controls and regulates the design, construction, operation, maintenance, and quality control of public drinking water systems to provide a degree of assurance that such systems are protected from contamination and maintained free from contaminants, which may injure the health of the consumer.

Environmental Protection and Health Act of 1972 (Title 39, Chapters 1 and 36): This act maintains the existing high quality of the state's ground water and satisfies existing and projected future beneficial uses, including drinking water, agricultural, industrial, and aquacultural water supplies. All ground water shall be protected as a valuable public resource against unreasonable contamination or deterioration.

Water Quality Standards (IDAPA 58.01.02), Water Quality Limited Streams: The Clean Water Act of 1972 was created "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters." Under section 303(d) of the act, state agencies are required to establish water quality standards and develop lists of streams that do not meet such standards. The integrated report is a consolidated listing and reporting of the state's water quality status pursuant to Sections 303(d), 305(b), and 314 of the Clean Water Act.

Water Quality Management Planning for Water Quality Limited Streams: As directed by the Clean Water Act, each state agency must develop a total maximum daily load (TMDL) for all the waters identified in the Section 303(d) list of impaired waters. A total maximum daily load determines pollutant reduction targets and usually covers a basin or subbasin. In instances where total maximum daily loads include National Forest System lands, the Forest Service is listed as a designated management agency and is relied upon for creating water quality management plans that identify strategies and actions to attain water quality standards.

State of Idaho Antidegradation Policy (IDAPA 58.01.02.051): Requires that existing beneficial uses be maintained and protected on all water bodies in the State of Idaho.

Idaho Department of Lands

Idaho Forest Practices Act of 1974, as amended (Title 38, chapter 13, Idaho Code): This act was created to assure the continuous growing and harvesting of forest tree species and to protect and maintain the forest soil, air, water resources, wildlife, and aquatic habitat. The rules pertaining to water quality and stream protections are also incorporated as best management practices within the Idaho Water Quality Standards.

State and Local Plans

Idaho Ground Water Quality Plan (Ground Water Quality Council 1996) The Plan is intended to protect ground water quality for public use and provide guidance to state agencies, local governments, and citizens to prevent ground water contamination. The Plan establishes the basis for protecting ground water now and for future generations and preventing contamination whenever possible. The plan also helps agencies develop management programs and regulations and implement ground water quality protection strategies. It is intended to work in conjunction with the Idaho State Water Plan.

Idaho State Water Quality Management Plan: The Plan is not a single plan or document but rather a compilation of the guidance and programs Idaho Department of Environmental Quality uses to implement Clean Water Act requirements. It describes how the state's water resources are managed and by what method Idaho manages water quality. The Plan follows a continuing planning process and outlines laws, rules, and guidance; water quality programs; monitoring and assessment; implementation; planning; and public involvement. https://www.deq.idaho.gov/water-quality/planning-and-administration/

Idaho Comprehensive State Water Plan (Idaho Department of Water Resources 2012): The plan includes the statewide water policy plan and associated component basin and water body plans, which cover specific geographic areas of the state. The Plan guides the development, management, and use of the state's water and related resources.

Community Source Water Protection Plans: a written plan a community develops to document its source water protection activities, which outlines the management tools the local community plans to use to protect drinking water sources.[15]

Methodology

Spatial and Temporal Scale

This programmatic Land Management Plan analysis focuses on broad scale estimated effects related to water resources on National Forest System lands. The analysis area for water resources include all the lands within the boundary of the Nez Perce-Clearwater. This area represents where changes may occur as a direct result of Forest Service management actions. The cumulative effects analysis area includes Nez Perce-Clearwater lands and adjacent jurisdictions and landowners.

The temporal scale for this analysis is the anticipated life of the Land Management Plan.

Analysis Methods and Assumptions

This analysis draws upon the best available literature citations that were found to be relevant to the ecosystems on the Nez Perce-Clearwater. Literature sources that were the most recent, peer-reviewed, and local in scope or directly applicable to the local ecosystem were selected. Uncertainty and conflicting literature were acknowledged and interpreted when applicable. Much of the best available science information (BASI) for water resources is summarized in the Northern Region Aquatic and Riparian Conservation Strategy (U.S. Department of Agriculture 2022e). The Aquatic Ecosystems and Fisheries Environmental Ecosystems Introduction provides a detailed discussion of the latest and best available science related conditions and management within riparian areas and water quality attributes, such as stream temperature and sediment.

Other sources of information used to support the analysis include Nez Perce-Clearwater geographical information systems data and geospatial data from other federal agencies and the State of Idaho. Spatial analysis used for delineating water resources used the Watershed Boundary Dataset (WBD) (U.S. Geological Survey and U.S. Department of Agriculture 2013) and the National Hydrography Dataset plus High Resolution (NHDplus HR) (U.S. Geological Survey 1999). The U.S. Fish and Wildlife Service (FWS) is the principal U.S. Federal agency tasked with providing information to the public on the status and trends of the Nation's wetlands. The FWS National Wetlands Inventory (NWI) is a publicly available resource that provides detailed information on the abundance, characteristics, and distribution of United States wetlands. See Appendix K for additional information that was used for the Final Environmental Impact Statement analysis.

The approach used in this analysis is to take a programmatic look at the outcomes that may result from implementing the proposed management direction in each alternative. For estimating the effects at the programmatic Land Management Plan level, the assumption has been made that the types of resource management activities allowed under the plan's direction are reasonably foreseeable future actions to achieve the goals and objectives. However, the specific location, design, and extent of such activities are not known at the time plans are revised. Project-level decisions are made based on site-specific analysis at the project-level basis. Therefore, the discussions within this section refer to the potential for the effect to occur and are, in many cases, only estimates. The effects analyses are useful when comparing and

[15] https://www.arcgis.com/home/webmap/viewer.html?webmap=7f060efe0339438690b91f79ff458c70&extent=-126.0742,40.6103,-101.7725,49.8065

evaluating alternatives but are not intended to be applied directly to specific locations on the Nez Perce-Clearwater.

Given that the site specificity of future activities are not known at the programmatic plan level, the potential spatial and temporal effects to water resources cannot be attributed to any specific watershed, nor can quantitative estimates of potential effects to water resources be determined, such as changes in water quantity. Broad scale estimated effects and trends related to hydrologic function and watershed processes for National Forest System lands within the project area have been qualitatively estimated. Cumulative effects to water resources are described in terms of their potential to generally affect trends on the subbasin to basin scale, across multiple land ownerships.

Reference conditions, often characterized by natural range of variation (NRV), provide a scientific basis for understanding forests, and a framework for understanding forest conditions and ecological processes prior to extensive human influence. Reference conditions provide a best estimate of a functional and sustainable system, and are a useful basis for developing desired conditions while accounting for uncertainties (for example, climate change). The range of natural variability differs across the Nez Perce-Clearwater because landscapes vary widely in geomorphology, soils, elevation, aspect, and vegetation composition, structure, and pattern.

Functional restoration focuses on the underlying processes that may be degraded, regardless of the structural condition of the ecosystem. Functionally restored ecosystem may have a different structure and composition than the historical reference condition. As contrasted with ecological restoration that tends to seek historical reference condition, the functional restoration focuses on the dynamic processes that drive structural and compositional patterns. Functional restoration is the manipulation of interactions among process, structure, and composition in a degraded ecosystem to improve its operations. Functional restoration aims to restore functions and improve structures with a long-term goal of restoring interactions between function and structure. It may be, however, that a functionally restored system will look quite different than the reference condition in terms of structure and composition and these disparities cannot be easily corrected because some threshold of degradation has been crossed or the environmental drivers, such as climate, that influenced structural and (especially) compositional development have changed (Forest Service Handbook 1909.12 section 05).

The water resources section uses the terms watershed, subwatershed, and priority watershed. In some cases, “watershed” is used generically to denote the drainage area that contributes runoff to a common point. In other cases, it refers to the hydrologic unit code (HUC) and level based on a hierarchical system (U.S. Geological Survey and U.S. Department of Agriculture 2013). Subwatersheds (Hydrologic Unit Code [HUC] 12s) typically comprise areas of approximately 10,000 to 40,000 acres and watersheds (HUC10s) drain areas of about 40,000 to 250,000 acres. Priority watersheds refer to subwatersheds that are identified for restoration emphasis through the watershed condition framework process (U.S. Department of Agriculture 2011d).

Measurement Indicators

The following indicators were used to compare and contrast differences between alternatives associated with water resources:

Watershed condition – This indicator addresses overall health of subwatersheds (HUC12) as classified through the Watershed Condition Framework program. It is measured by the number of potential Priority Watersheds improved to a better functioning condition class.

Water quality – This indicator addresses the expressed alteration of physical, chemical, and biological components of water quality. It is measured qualitatively by evaluating potential changes in sediment delivery, stream water temperature, and contaminates; as well as potential changes to the amount of streams not meeting beneficial uses and/or amount of streams classified as water quality impaired.

Water quantity – This indicator addresses changes to the natural flow regime with respect to the magnitude, duration, or timing of the natural streamflow hydrograph. It is measured qualitatively by potential changes in forested vegetation openings; hydrologic connectivity of roads to streams, and consumption of public water supply.

Riparian areas, wetlands, and floodplain function – This indicator addresses the potential for alteration of these geomorphic features and sensitive ecosystems. It is measured qualitatively by potential changes in riparian and wetland conditions and floodplain function.

Affected Environment

General Description

The Nez Perce-Clearwater contains portions of fourteen subbasins that drain primarily into the Salmon River and Clearwater River Basins and, to a lesser extent, the Snake River and Spokane River Basins (Figure 33, Table 114). All rivers and streams on the Nez Perce-Clearwater eventually drain into the Spokane and Snake Rivers, which flow into the Columbia River. The Lochsa River and Lower Selway River subbasins are completely contained within Nez Perce-Clearwater lands.

The Nez Perce-Clearwater is located primarily within the Clearwater and Salmon River basins. The Salmon River is an unregulated, free-flowing river that originates in mountain ranges in Idaho and western Montana and flows about 410 miles through central Idaho before joining with the Snake River in lower Hells Canyon. Peak flows in the Salmon River generally occur in May and June during snowmelt runoff. About 90 percent of the Salmon River Basin is comprised of federal lands, including about 77 percent National Forest System lands and 13 percent Bureau of Land Management lands. Nearly 80 percent of the land cover is forested. Key geologic features in the Salmon River Basin are the Idaho Batholith and Challis volcanics that tend to produce coarse, sandy soils that are highly erodible when weathered (King et al. 2004). The combination of these soils, steep topography, and climatic stresses gives rise to significant base surface erosion, slumping, and debris avalanche hazards (Megahan and Molitor 1975, Quigley and Arbelbide 1997a, Quigley 1997).

The Clearwater River originates in the Bitterroot Mountains at the border of Idaho and Montana and flows westward to its confluence with the Snake River at Lewiston, Idaho. Major tributaries to the Clearwater River include the Lochsa, Selway, North Fork Clearwater, South Fork Clearwater, and Potlatch Rivers. Streamflow in the Clearwater River typically peaks in May and June in response to snowmelt runoff. Highly erodible igneous rocks underlay a large part of the Clearwater River Basin (King et al. 2004). As a result, much of the basin is highly susceptible to erosion and subsequent sediment transport.

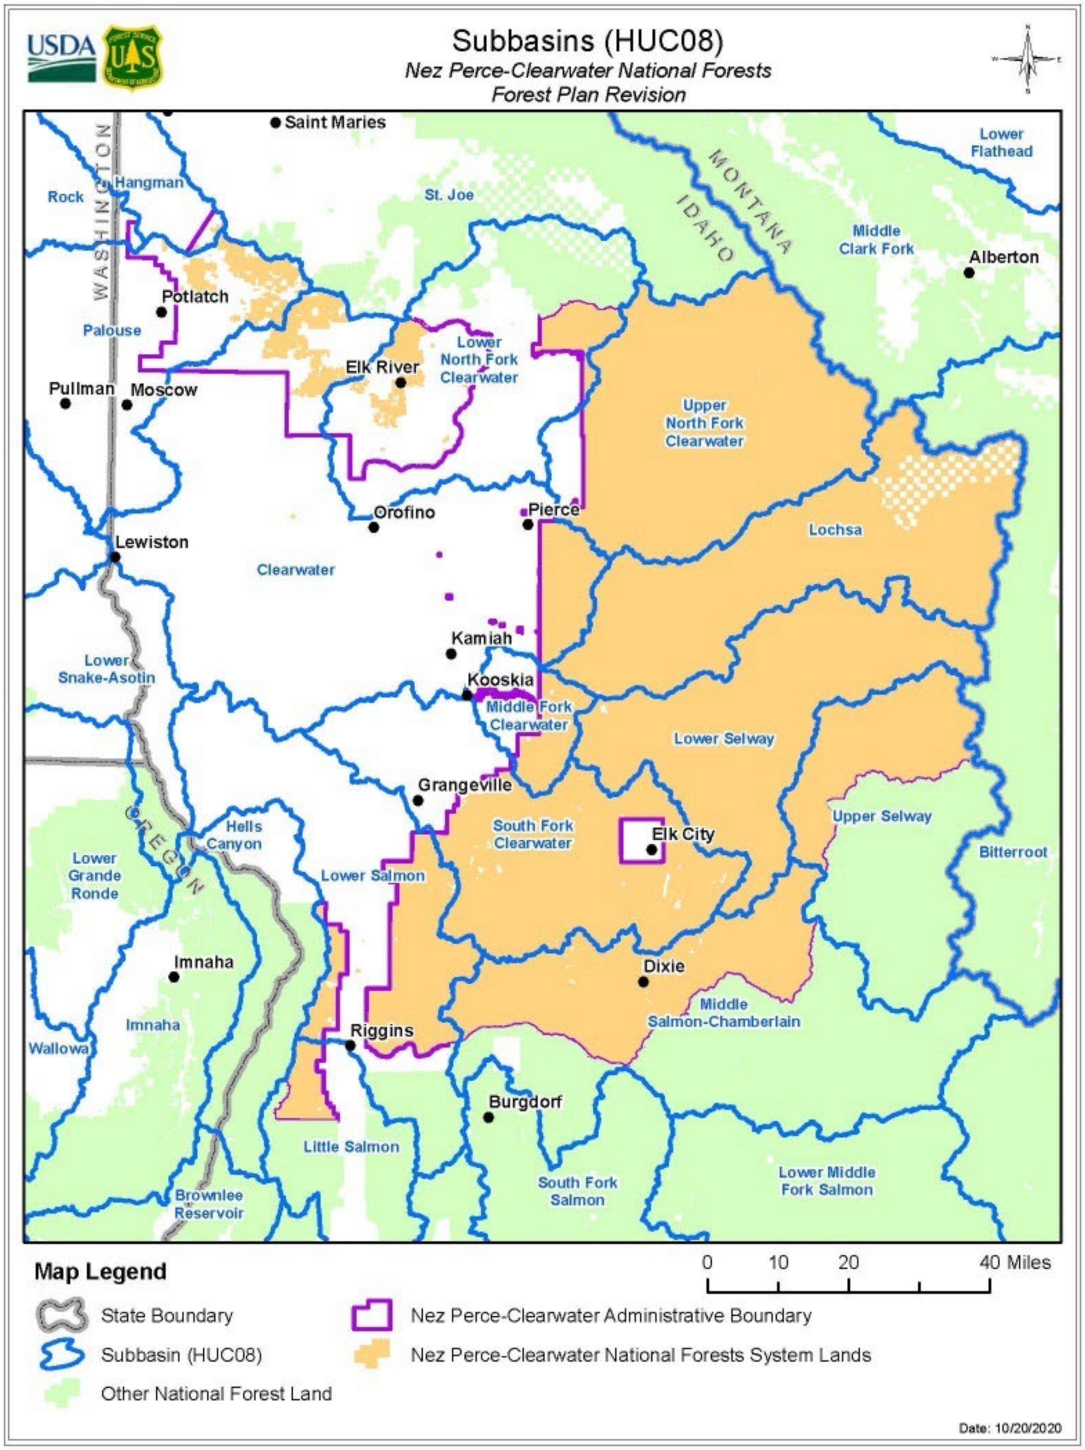

Figure 33. Subbasins (HUC08) located within the plan area

Data Source: Nez Perce-Clearwater Geographic Information System.

Table 114. Subbasins in the Nez Perce-Clearwater and associated acres

Basin	Hydrologic Unit Code (HUC08)	Subbasin	Subbasin Acres	Nez Perce-Clearwater Acres	Percent Nez Perce-Clearwater lands within subbasin
Spokane River	17010306	Hangman	443,035	9,542	2
Lower Snake River	17060108	Palouse	1,486,461	102,416	7
Lower Snake River	17060109	Rock	610,823	4,339	1
Clearwater River	17060301	Upper Selway	629,438	241,276	38
Clearwater River	17060302	Lower Selway	656,688	656,918	100
Clearwater River	17060303	Lochsa	755,727	756,059	100
Clearwater River	17060304	Middle Fork Clearwater	139,705	73,713	53
Clearwater River	17060305	South Fork Clearwater	754,025	525,688	70
Clearwater River	17060306	Clearwater	1,507,889	142,402	9
Clearwater River	17060307	Upper North Fork Clearwater	829,355	788,125	95
Clearwater River	17060308	Lower North Fork Clearwater	734,145	90,601	12
Salmon River	17060207	Middle Salmon-Chamberlain	1,095,488	412,291	38
Salmon River	17060209	Lower Salmon	755,356	226,967	30
Salmon River	17060210	Little Salmon	369,150	40,668	11

Data Source: Nez Perce-Clearwater Geographic Information System.

The combined Lochsa and Selway Rivers drain about 46 percent of the Clearwater River Basin, draining areas that are essentially 100 percent forested. The subbasins are 95 percent contained within Nez Perce-Clearwater and Bitterroot National Forest lands. Underlain by the Idaho Batholith, the Lochsa and Selway drainage basins are characterized by rock that weathers deeply to produce coarse, sandy soils; if disturbed, these soils have high erosion rates (King et al. 2004).

The terrain varies greatly across the Nez Perce-Clearwater. Breaklands have very steep, straight tributaries with high sediment delivery efficiency. Rolling uplands have gentle slopes with complex dendritic and structurally controlled drainage patterns with low sediment delivery efficiencies. Mountains are steep and dissected, with narrow valleys.

Elevation ranges from about 1,400 feet to over 8,000 feet on the higher peaks. The climate of the Nez Perce-Clearwater varies with location. Generally, the climate in the northern portion of the Nez Perce-Clearwater is maritime-influenced with a cool-to-warm temperate and dry summers. The southern portion of the Nez Perce-Clearwater is more influenced by the dry Rocky Mountain climatic patterns.

Precipitation also varies seasonally, with little occurring during the summer months. Average annual precipitation ranges from 25 inches in low elevation valleys to 60 to 80 inches at the upper elevations.

The majority of precipitation falls as snow between October and April. Due to colder average temperatures, winter precipitation above 4,000 feet falls largely as snow that may remain through late spring to early summer. Below 4,000 feet, a higher probability of winter precipitation falling as rain occurs with subsequently reduced storage duration. The transition area just above and below the 4,000-foot elevation band also defines the rain-on-snow zone, an area susceptible to rapid melting and extreme runoff events. Rain-on-snow events can occur from November through March.

Hydrology across the Nez Perce-Clearwater varies largely as a result of differences in amount and form of precipitation, such as snow versus rain, which is intrinsically linked to variations in elevation and climatic patterns. The timing of peak stream flow across the Nez Perce-Clearwater is variable, occurring from April through June depending on the drainage. Base flows occur most often in August and September, corresponding with times when instream temperatures are highest and precipitation is lowest.

Based on the U.S. Geological Survey National Hydrography Dataset, there are 4,565 miles of perennial fish bearing streams, 4,746 miles of perennial non-fish bearing streams, and 4,995 miles of intermittent streams located within the Nez Perce-Clearwater administrative boundary. According to the U.S. Fish and Wildlife Service National Wetlands Inventory (U.S. Department of the Interior 2015b), there are 3,838 acres of ponds and lakes on the Nez Perce-Clearwater. Most are located in high elevation subalpine areas and range in size from less than 1 acre to the 117-acre Fish Lake near the Montana border. All lakes that have been assessed by the Idaho Department of Environmental Quality are meeting water quality standards and supporting beneficial uses (Idaho Department of Environmental Quality 2019, State of Idaho Department of Environmental Quality 2022b).

There are nine known geothermal hots springs located on the Nez Perce-Clearwater – Cow Flats, Red River, Running Creek, Stanley, Jerry Johnson, Little Jerry Johnson, Weir Creek, Colgate, and an unnamed spring 0.5 miles east of Colgate hot springs. The Red River hot springs is the only developed site and is used for commercial purposes. The water temperatures range from 106 to 138 degrees Fahrenheit, with Cow Flats being the hottest.

There are two water regulating facilities adjacent to the Nez Perce-Clearwater. Dworshak Dam, constructed in 1972, is located two miles above the mouth of the North Fork Clearwater River. The impoundment area, Dworshak Reservoir, is 16,508 acres, of which only 670 acres occur on Nez Perce-Clearwater land. Elk River dam and Elk Creek reservoir are located near the town of Elk River. The outlet of the reservoir is less than 1,000 feet from the Nez Perce-Clearwater boundary.

Two dams occur within the Nez Perce-Clearwater, which are both classified as low hazard dams and are not currently being operated. Erickson Dam is located on Erickson Creek, which is a tributary to the South Fork of the Clearwater River. It is an earthen dam with a height of 20 feet and normal storage of 8 acre-feet. It currently has no functioning outlet controls. The closest downstream community from Erickson Dam is Elk City, Idaho, which is approximately ten miles away. Upper Bear Dam is located in the Selway-Bitterroot Wilderness on Bear Creek, which is a tributary to the Selway River. It is an earthen dam with a height of 13 feet and normal storage of 82 acre-feet. It currently has no functioning outlet controls. The closest downstream community from Upper Bear Dam is Lowell, Idaho, which is over 70 miles away.

Watershed Condition

Watershed Condition Framework

Watersheds and their ecological condition have been an increasingly important focus of public land managers in the last two decades (Reeves, Pickard, and Johnson 2016, Thomas et al. 2006, Esselman et al. 2011). Nationally, in 2011 the Forest Service introduced the Watershed Condition Framework (U.S. Department of Agriculture 2011d), a nationally consistent, comparable, and credible process for improving the health of watersheds on national forests and grasslands. The framework provides a method for classifying watershed condition at the Hydrologic Unit Code (HUC) 12 subwatershed scale and offers broad guidance to help national forests select priority watersheds.

The classification system considers 12 indicators that are surrogate variables representing the underlying ecological, hydrological, and geomorphic functions and processes that affect watershed condition. Watershed condition encompasses both aquatic and terrestrial components because water quality and aquatic habitat are inseparably related to the integrity and, therefore, the functionality of upland and riparian areas within a watershed. The approach is designed to foster integrated ecosystem-based watershed assessments, provide guidance to programs of work in watersheds that have been identified for restoration, enhance communication and coordination with external agencies and partners, and improve national-scale reporting and monitoring of program accomplishments. The watershed condition framework provides the Forest Service with an outcome-based performance measure for documenting improvements to watershed condition at forest, regional, and national scales (U.S. Department of Agriculture 2011d).

Watershed condition classification ultimately categorizes watersheds in one of three discrete classes that reflect the level of watershed functionality or integrity - 1) functioning properly, 2) functioning at risk, and 3) impaired function. In this framework, a watershed is considered in good condition if it is functioning in a manner similar to one found in natural wildland conditions (Karr and Chu 1999, Lackey 2001). This characterization would not be interpreted to mean that managed watersheds cannot be in good condition. A watershed in properly functioning condition has minimal undesirable human impact on natural, physical, or biological processes and is resilient and able to recover to the desired condition when or if disturbed by large natural disturbances or land management activities (Yount and Niemi 1990). By contrast, a watershed is classified as having impaired function when some physical, hydrological, or biological attributes indicate a degraded state. Substantial changes to the factors that caused the degraded state are commonly needed to set them on a trend or trajectory of improving conditions that sustain physical, hydrological, and biological integrity.

Watershed Conditions on the Nez Perce-Clearwater

Watershed conditions vary across the Nez Perce-Clearwater, ranging from those unaffected by direct human disturbance to those exhibiting various degrees of modification and impairment. In 2011, the Nez Perce-Clearwater completed the watershed condition classification for 220 subwatersheds. In summary, 140 subwatersheds were rated as Functioning Properly, 73 were rated as Functioning at Risk, and 7 were rated as having Impaired Function. See Appendix K for additional information related to watershed condition classification on the Nez Perce-Clearwater.

The roads and trails indicator had the highest amount of impaired function ratings, with 85 out of 220 subwatersheds classified as impaired. The roads and trails indicator takes into account road and trail density, road maintenance, proximity to water, and mass wasting potential. Sixty-three percent of subwatersheds on the Nez Perce-Clearwater were categorized as functioning at risk or impaired function for the roads and trails indicator. There are approximately 727 miles of system road located on areas identified as landslide prone. See the Aquatic Ecosystems and Fisheries Affected Environment section for a more detailed discussion of road related affects to water resources.

Most roads on the Nez Perce-Clearwater were constructed during the 1960s through the mid-1990s. Over time, maintenance levels have decreased due to reductions in funding and personnel, resulting in fewer miles of road being maintained annually and longer durations between maintenance activities for many of the roads. The rate of new road construction has slowed substantially, and new road construction is predominately limited to that needed for timber harvest access and road relocations for resource protection. A primary focus of the watershed restoration program from the late 1990s to 2010s was road decommissioning. Since 1999, a total of 1,625 miles of forest system and non-system roads have been decommissioned. See Infrastructure Section for the number of road miles decommissioned by year.

Road decommissioning has slowed in the last decade to maintain access. In 2015, a forest-level roads analysis (U.S. Department of Agriculture 2015e) was completed for the Nez Perce-Clearwater. The report provided an assessment of the road infrastructure and a set of findings and recommendations for adjustments to the Nez Perce-Clearwater transportation system.

The broad-scale Travel Analysis assessed 7,563 miles of road and identified 7,549 miles of road as “likely needed for future use”, which could be considered as an approximation of the minimum road system (U.S. Department of Agriculture 2015e). Approximately 14 miles of road, less than one percent of the road system, was identified as “not likely needed for future use” and may be considered candidates for conversion to another use, storage for future use, or removal through decommissioning. The report did note that site specific roads analysis and project level assessment would likely result in additional roads requiring storage for future use, reconstruction or relocation of the road, or additional road maintenance. The Travel Analysis acknowledged that current and projected road budgets are far from fully funding road maintenance needs. Lack of road maintenance funding may increase the risk of impacts on water quality and aquatic ecosystems, although Best Management Practices designed into projects could reduce much of this impact (U.S. Department of Agriculture 2015e).

The Travel Analysis also found that additional new road construction for local access may be needed in the future. Road construction needs would likely arise in areas where there is a need to reestablish access for vegetation management, where existing roads need to be relocated to mitigate impacts, or where access is needed for fire fuels treatments in wildland urban interface areas.

Forest roads that are maintained on an annual basis are typically those roads that have the most administrative and visitor use. Over the last 20 to 30 years, the Nez Perce-Clearwater has focused on road reconstruction and decommissioning as a primary strategy to reduce sediment delivery and potential road failures. Several roads have been relocated out of riparian areas. Culverts have been replaced and often upsized at stream crossings that were causing sediment delivery or impeding passage of aquatic organisms. More recently, additional drainage culverts have been installed, especially before and after perennial stream crossings, to drain ditches prior to entering perennial stream channels. Although there have been improvements in the overall road network, roads and stream crossings continue to cause impacts to watershed condition, riparian and wetland systems, and water quality.

Roads provide necessary motorized access for forest management, recreation, and other beneficial purposes (Gucinski et al. 2001), but they can also have detrimental effects on ecosystem function. The associated effects on watershed condition and riparian and wetland ecosystems differ based on topography, geology, slope stability, design, location, and use.

Designated wilderness and Idaho Roadless Areas cover just over 60 percent of the Nez Perce-Clearwater and natural ecological processes and disturbances dominate. Watersheds in these areas are in good condition and are functioning within the natural range of variation.

Priority Watersheds

Utilizing the Watershed Condition Framework process, in 2011 the Nez Perce-Clearwater designated four subwatersheds as priority watersheds – Upper Little Slate Creek, Upper Elk Creek, Upper Clear Creek, and Waw'aalamnime Creek (Fishing Creek). For each of these four subwatersheds, a watershed restoration action plan was developed to designate the essential projects necessary to restore the watershed to a better condition. Issues in these watersheds include exclusion of wildfire, departed vegetation conditions, road location and densities, undersized culverts, past mining impacts, riparian structure and function, invasive species, loss of soil productivity, and water quality.

In 2014, the Upper Newsome Creek and Meadow Creek subwatersheds were added to the list of designated priority watersheds. To date, all restoration work in the watershed restoration action plans has been completed in the Waw'aalamnime Creek, Upper Newsome Creek, and Meadow Creek subwatersheds. The majority of the restoration work was accomplished through partnership with the Nez Perce Tribe. Work in the Upper Elk Creek, Upper Clear Creek, and Upper Little Slate subwatersheds is ongoing. In 2023, the Musselshell Creek and Lower Crooked River subwatersheds were identified as priority watersheds.

The Agricultural Improvement Act of 2018 (a.k.a., the 2018 Farm Bill), Section 8405 permanently authorizes the Forest Service to develop and maintain the Watershed Condition Framework, using the agency's existing processes and criteria. It provides specific legislative authorization and requirements for the process, one of those being to identify for protection and restoration up to 5 priority watersheds in each National Forest.

Water Quality

Forests and grasslands often produce high-quality water. Long- term studies have shown this to be generally true in undisturbed ecosystems and for some classes of land use (Sedell et al. 2000). Other forms of land use have been found to degrade water quality to varying degrees. The most notable water quality problems found on national forests are typically sediment (turbidity and bedload), nutrients, and temperature. Measures to protect, restore, or mitigate water quality have been devised for many management practices. The Aquatic Ecosystems and Fisheries Environmental Ecosystems Introduction provides a detailed discussion of the latest and best available science related to conditions and management within riparian areas and water quality attributes, such as stream temperature and sediment.

The goal of the Clean Water Act is "to restore and maintain the chemical, physical, and biological integrity of the nation's water." The Idaho Department of Environmental Quality uses water quality standards (Idaho Administrative Procedures Act [IDAPA] 58.01.02) to determine if Idaho's waters are being adequately protected and is responsible for ensuring that Idaho's surface, ground, and drinking water resources meet those standards. A water quality standard defines the goals that have been set for a water body by designating uses for the water, sets criteria necessary to protect those uses, and prevents degradation of water quality. A memorandum of understanding (20-MU-11046000-011) has been established to document coordination between the Idaho Department of Environmental Quality and the U.S. Forest Service in Idaho to implement the nonpoint source water quality provisions of the federal Clean Water Act for the State of Idaho (U.S. Department of Agriculture 2020c).

Beneficial Uses

Beneficial uses are the desired uses that water bodies should support, as identified in Section 100 of Idaho's water quality standards (IDAPA 58.01.02.100). Each beneficial use has a unique set of water quality requirements or criteria that must be met for the use to be supported. Most water bodies have multiple beneficial uses. A water body is considered impaired when it does not meet the water quality criteria needed to support one or more of its beneficial uses. Beneficial uses that pertain to water bodies on the Nez Perce-Clearwater include cold water aquatic life, salmonid spawning, primary contact recreation, secondary contact recreation, domestic water supply, agricultural, industrial, wildlife habitats, and aesthetics uses. See Appendix K for additional information regarding beneficial uses.

Idaho Department of Environmental Quality 303(d) and 305(b) Integrated Report

The Idaho Department of Environmental Quality 303(d) and 305(b) Integrated Report is a compilation of information regarding the water quality status of all Idaho waters and is a requirement of the Clean Water Act. Integrated reports are compiled biennially and are submitted to the U.S. Environmental Protection Agency for approval. There are two main parts to the integrated report: 1) the 305(b) list, which summarizes the current condition of all state waters, and 2) the 303(d) list, which identifies those waters that are impaired or water quality limited and for which a total maximum daily load assessment is required. Both lists are named in accordance with the sections of the Clean Water Act where they are defined. Impaired waters listed on the 303(d) list are simply a subset of those on the 305(b) list. The Integrated Report places all state water bodies into one of five primary categories, which are described in Table 115. These categories describe how a water body relates to its beneficial uses. Streams not supporting beneficial uses do not meet applicable water quality standards for their designated beneficial uses and are termed impaired or water quality limited. They are assigned Category 4 or 5 designations. Impairments in streams on the Nez Perce-Clearwater include sediment, stream temperature, *E. coli*, flow regime alterations, physical substrate habitat alterations, combined biota, and habitat bioassessments**.**

The most current U.S. Environmental Protection Agency approved report is the 2022 Idaho Department of Environmental Quality 303(d) and 305(b) Integrated Report (State of Idaho Department of Environmental Quality 2022a). Table 115 displays the amount of stream miles on the Nez Perce-Clearwater by category. Approximately 51 percent of streams are fully supporting or presumed to be fully supporting beneficial uses, 19 percent of streams have not been assessed, and 30 percent of streams are not supporting one or more beneficial uses. All assessed lakes on the Nez Perce-Clearwater are fully supporting beneficial uses. See Appendix K for more information regarding water quality.

Table 115. Integrated Report categories and miles occurring on the Nez Perce-Clearwater

Category	Description	Assessed Miles
1	Waters are wholly within a designated wilderness or Idaho roadless area and presumed to be fully supporting all beneficial uses.	1,458
2	Waters are fully supporting those beneficial uses that have been assessed	2,610
3	Waters have insufficient or no data and information to determine if beneficial uses are being attained or not.	1,505
3T	Waters are wholly or partially on Indian reservations and not subject to the state's 305(b) and 303(d) reporting requirements	6
4A	Waters do not support one or more beneficial uses but a total maximum daily load is completed and approved by the Environmental Protection Agency.	1,345
4C	Waters do not support one or more beneficial uses. Waters are those failing to meet applicable water quality standards due to other types of pollution, such as habitat or flow alteration, and, thus, a total maximum daily load is not required.	329
5	Waters do not meet applicable water quality standards for one or more beneficial uses due to one or more pollutants. These waters make up the 303(d) list and an Environmental Protection Agency approved total maximum daily load is required.	747

Data Source: Idaho Department of Environmental Quality 303(d) and 305(b) Integrated Report (State of Idaho Department of Environmental Quality 2022a)

Total Maximum Daily Load

As directed by the Clean Water Act, each state agency must develop a total maximum daily load for all waters identified on the section 303(d) list of impaired waters. Total maximum daily loads provide an approach to improving water quality so that streams and lakes can support and maintain their state-designated beneficial uses. A total maximum daily load determines pollutant reduction targets and usually covers a basin or subbasin. In instances where a total maximum daily load assessment includes National Forest System lands, the Forest Service serves as a designated management agency through governmental memoranda of understanding. The State of Idaho is the lead agency for total maximum daily load development but must get U.S. Environmental Protection Agency approval before the total maximum daily load is formalized. Total maximum daily loads for a pollutant is defined by the EPA as the sum of the waste load allocation for point sources, plus load allocation for nonpoint sources of pollution, plus a load to allow a margin of safety (40 CFR 130.2). The load allocation for nonpoint sources of pollution includes "natural" background loads and the margin of safety accounts for uncertainty. The TMDL approach is a mechanism for improving impaired waters and a process for determining tradeoffs between point and nonpoint sources. It provides a focus for future watershed management actions.

Category 4A waters do not support one or more beneficial uses but a total maximum daily load is completed and approved by the Environmental Protection Agency. Table 116 displays which subbasins have completed subbasin assessment and total maximum daily loads established for Category 4A streams. Only four of the subbasins have an associated TMDL implementation plan developed. See Appendix K for more information regarding total maximum daily loads.

Table 116. Status of subbasins in the total maximum daily load (TMDL) process.

Status	Subbasins
Completed subbasin assessment and TMDL established; no TMDL implementation plan developed	Lower Selway, Middle Salmon River–Chamberlain Creek, Lower Salmon River, Palouse River (South Fork Palouse River and

Status	Subbasins
	Palouse River tributaries), Clearwater River (Lolo Creek Tributaries), Hangman Creek, Upper North Fork Clearwater River, Lochsa River
Completed subbasin assessment and TMDL established; TMDL implementation plan completed	Clearwater River (Potlatch River), Little Salmon River, South Fork Clearwater River, Lower North Fork Clearwater

Data Source: Idaho Department of Environmental Quality Table of Subbasin Assessments, Total Maximum Daily Loads, Implementation Plans, and Five-Year Reviews; http://www.deq.idaho.gov/water-quality/surface-water/tmdls/table-of-sbas-tmdls/.

A Total Maximum Daily Load must be established and approved by Environmental Protection Agency for the 747 miles of Category 5 water bodies in the Palouse, Lochsa, Middle Fork Clearwater, Clearwater, Upper North Fork Clearwater, and Lower North Fork Clearwater rivers that are listed in the 2022 Idaho Department of Environmental Quality 303(d) and 305(b) Integrated Report (State of Idaho Department of Environmental Quality 2022b) before a TMDL implementation plan can be developed.

State of Idaho Antidegradation Policy

The State of Idaho Antidegradation Policy (IDAPA 58.01.02.051), requires that existing beneficial uses be maintained and protected on all water bodies. Under the antidegradation standard, Idaho has a three-tier policy with varying levels of protection – 1) unremarkable waters, 2) high quality waters, and 3) outstanding resource waters. All waters receive Tier I protection. Water bodies identified in the Integrated Report as fully supporting assessed uses are provided Tier II protection. Waters given Tier III protection are outstanding resource waters. The Idaho State Legislature has yet to designate any river in Idaho as an outstanding resource water. Approximately 70 percent of waterbodies on the Nez Perce-Clearwater have Tier II protection, while 30 percent of streams that are not meeting beneficial uses (Table 115) have Tier 1 protection.

Stream Channel Protection

The Idaho Stream Channel Protection Act regulates stream channel alterations between mean and high-water marks on perennial streams in Idaho. Instream activities on National Forest System lands must adhere to the rules pertaining to the act by obtaining a stream channel alteration permit from the Idaho Department of Water Resources before commencing a streambank or stream channel altering activity. A memorandum of understanding (18-MU-110156000-080) has been established to document coordination between the Idaho Department of Water Resources and the U.S. Forest Service in Idaho to implement the Idaho Stream Channel Protection Act within Idaho on lands administered by the U.S. Forest Service (U.S. Department of Agriculture 2018b).

Best Management Practices

Best management practices (BMP) are methods, measures, or practices used to address the Clean Water Act objective of maintaining and restoring the chemical, physical, and biological integrity of the nation's waters. The use of BMPs is the primary mechanism for mitigating impacts to resources from Nez Perce-Clearwater management actions. BMPs used on the Nez Perce-Clearwater come from federal and state direction. See Appendix K for additional information on BMPs, including a summary of BMP reviews for Idaho Forest Practices Act compliance and the Forest Service National Core Best Management Practice program.

Water Quantity

Watershed condition is a primary driver in determining the magnitude, frequency, and timing of runoff from a watershed. The quantity and timing of streamflow are critical components of water supply, water quality, and the ecological integrity of river systems (Hill et al. 1991). In the absence of major disturbance, stream channels are typically dynamically in balance with the stream's flow regime, which is a key determinant of the energy available for erosion, transport, and deposition of sediment within channels. Increased water yields may be associated with increased probability of peak flow events, which could lead to increased channel and bank adjustment through scour, bedload movement, or redistribution of sediment in depositional areas.

Timber harvest has occurred on the Nez Perce-Clearwater for over a century, , starting in the late 1890s on the Nex Perce (Cochrell 1970) and early 1920s on the Clearwater (Space 1981). It has long been recognized that removal of forest vegetation may alter watershed hydrologic processes. Lee Silvey, a retired Nez Perce National Forest hydrologist, is credited as being the primary author of Forest Hydrology Part II (U.S. Department of Agriculture 1974a), a seminal publication outlining the methodology for water yield analysis associated with forest vegetation manipulation. This methodology or variants of it are still widely used throughout national forests in the U.S. Forest Service Northern Region and beyond.

Best available scientific literature has converged upon a 20 percent change in forest canopy extent as commonly producing a detectable change in peak flows and/or average annual water yield(MacDonald and Stednick 2003, Grant et al. 2008, Troendle et al. 2010). It is important to note that persisting extent of cleared forest vegetation, even if it were greater than 20 percent of a watershed's area, may not reflect a departure from the naturally occurring extent of early successional vegetation in light of natural disturbance processes across the Nez Perce-Clearwater. This, in turn, suggests that hydrograph dynamics should not be characterized as departed from the natural range of variability in light of existing cleared area.

A geographic information system analysis was conducted to provide a general idea as to how much area may currently be in a cleared or open condition. Early successional forested vegetation extent, defined as size class 0 to 4.9 inches diameter at breast height, was collated for each Hydrologic Unit Code (HUC) 12 subwatershed managed by the Nez Perce-Clearwater. This exercise did not differentiate between early successional vegetation resulting from natural disturbances or past management activities. Using this simplified approach, existing cleared area for HUC12 subwatersheds across the Nez Perce-Clearwater ranges from 1 to 12 percent. It is important to note that this analysis did not account for cleared area associated with roads, which generally occupy less than three percent of a subwatershed area.

Maintaining connectivity between hillslope flow regimes and floodplains and connectivity between floodplains and stream channels allows water to be absorbed and stored, increasing the likelihood of sustaining late season flows. Productive soils and intact ground cover capture and store water, slowly releasing it to groundwater and downstream sources. This provides critical regulation of water quality, and quantity, including the attenuation of flood flows (Neary et al. 2009, Shannon et al. 2019).Beyond contributing to reductions in forest cover, road densities may affect near-surface lateral flow pathways and watershed drainage density, which can alter timing and magnitude of streamflow (Wemple and Jones 2003). Road densities range from less than 1 to 6.2 miles per square mile for the HUC12 subwatersheds and are generally higher in the more managed portion of the Nez Perce-Clearwater. Approximately 14 percent of the HUC12 subwatersheds have road densities over 3 miles per square mile and 33 percent have road densities ranging between 1 to 3 miles per square mile. Trail densities for the HUC12 subwatersheds range from 0 to 2.6 miles per square mile. Approximately 18 percent of HUC12 subwatersheds having trail densities over 1 mile per square mile.

Consumptive water rights for surface or ground water can also affect water quantity. Idaho Department of Water Resources manages water in the State of Idaho through water allocation and distribution processes. Water rights authorize the withdrawal of public water by private individuals and organizations and are enforced by the state. Water rights on the Nez Perce-Clearwater are administered by the Forest Service

Northern Region regional office in close coordination with the State of Idaho. See Appendix K for more information on water rights on the Nez Perce-Clearwater.

Riparian Areas, Wetlands, and Floodplain Function

Riparian areas, wetlands, and floodplains are the interface between terrestrial and aquatic ecosystems and are an integral part of watersheds. Consequently, the health of these areas is closely interrelated to the condition of the surrounding watershed and an indicator of overall ecosystem quality (DeBano and Schmidt 1989, Hornbeck and Kochenderfer 2000).

Patterns of riparian and wetland ecosystems vary from relatively narrow strips of land along perennial and intermittent streams in deeply incised, steep mountain valleys to meadows and adjacent wetlands within the wider floodplains of major rivers. Riparian and wetland areas are widely distributed across the Nez Perce-Clearwater and occur at all elevations. The National Wetland Inventory identifies approximately 53,465 acres of riparian and wetland area on the Nez Perce-Clearwater (U.S. Department of the Interior 2015b). Portions of the Nez Perce-Clearwater have not been fully mapped so these acres are a conservative estimate. An evaluation using geographical information system spatial information and data identified approximately 295,000 acres of riparian areas, wetlands, and floodplains on the Nez Perce-Clearwater. Although riparian ecosystems only cover approximately seven percent of the Nez Perce-Clearwater, their ecological significance within the landscape exceeds their limited distribution.

Riverine systems in the Nez Perce-Clearwater vary in steepness, width, stream flow, sediment deposition, and erosive characteristics. This becomes readily apparent as one moves downstream from narrow head-water streams to lower gradient streams with wider floodplains. The natural functions that are associated with a particular floodplain depend in part on its location within this continuum. Floodplains have been shaped, and continue to be shaped, by dynamic physical and biological processes driven by climate, the hydrologic cycle, erosion and deposition, extreme natural events, and other forces.

Floodplain functions, such as flood water storage and conveyance, protection of water quality, and groundwater recharge, are hydrologically important components of a watershed. When rivers are connected to their floodplains, channels are able to migrate naturally. During high flow events, water is distributed across floodplains, dissipating hydraulic energy and increasing the exchange of nutrients and organic material between aquatic and riparian ecosystems. Floodplains also provide an expanded area for deposition and storage of excess sediment, particularly fine sediment, from streams during overbank flow events. Additionally, the water storage and recharge function of floodplains ensures a source of cold water in summer months and warmer water during winter months. Water seeps into the groundwater table during floods, recharging wetlands, off-channel areas, and shallow aquifers. In turn, these areas release water to streams during the summer months. Without this recharge, flows are typically lower and water is warmer.

Functioning riparian and wetland systems are dynamic and more resilient to disturbances from natural and human-caused events than impaired systems. Functioning riparian areas and wetlands have lateral, longitudinal, and drainage network connections, connecting uplands to riparian areas, groundwater to surface water, and streams to floodplains. As defined in Potyondy and Geier (2011), riparian and wetland areas function properly when they: have adequate vegetation present to dissipate stream energy associated with high water flow, thereby reducing erosion and improving water quality; improve flood-water retention and ground-water recharge; provide shade to moderate stream temperatures; develop root masses that provide streambank stability; supply large woody debris to streams for pool development and sediment entrapment; sequester carbon; filter pollutants; and contribute to nutrient cycling.

Riparian and wetland vegetation is an indicator assessed in the Watershed Condition Framework analysis (U.S. Department of Agriculture 2011d). Based on the Nez Perce-Clearwater 2011 classification, 56 percent of the 220 subwatersheds classified were rated Functioning Properly for this attribute. Approximately 26 percent of subwatersheds were scored as Functioning at Risk and 18 percent of subwatersheds were rated as having Impaired Function. The functioning at risk and impaired subwatersheds have areas where water tables are disconnected from the adjacent riparian areas, primarily due to roads; alteration of near-surface hydrologic processes; and vegetation that reflects the loss of available soil water. See the Aquatic Ecosystems and Fisheries Affected Environment section and Aquatic, Wetland, Water, and Riparian Habitats in the Wildlife section for a more detailed discussion of riparian vegetation.

Disturbances are a natural part of the riparian environment and derive both from fluvial processes (for example, large floods and ice scour) and more general terrestrial ones (for example, wildfire, landslides, and wind storms) (Montgomery and Buffington 1997, Bendix and Hupp 2000). Factors that may have interrupted hydrologic function or contributed to a decrease in riparian and wetland conditions on the Nez Perce-Clearwater include concentrated livestock grazing, current and historic mining, historic timber harvest, road construction and road use, water diversions, removal of beavers, invasive plant species infestations, and disturbances associated with recreational use. These types of management activities have altered conditions by altering flow regimes, disrupting sediment and wood material transport downstream, altering channel morphology, and changing plant communities. A variety of timber harvest treatments have occurred in riparian areas in the past. Most of those harvested areas have revegetated as a result of planting or natural regeneration. Historically, it was acceptable for system roads, temporary roads, and skid trails to be constructed close to stream channels. Localized sedimentation and temperature increases are likely to have occurred. Natural recovery, active restoration, and limitations to the type of harvest and associated infrastructure allowed have mitigated or improved riparian conditions that were impacted by these past actions. See the Aquatic Ecosystems and Fisheries Affected Environment section for a more detailed discussion on riparian conditions due to roads, livestock grazing, fire, and historic dredge mining.

Natural disturbance in riparian areas, including wildfire, insects, disease, flooding, drought, and weather events such as windstorms, may temporarily degrade conditions but these disturbances are necessary for the regeneration of many native plant species. Aggressive fire suppression over the last 100 years has to some extent altered natural disturbance regimes within riparian systems, particularly in the more managed portions of the Nez Perce-Clearwater. With the addition of PACFISH and INFISH amendments to the existing forest plans in 1995, little to no vegetation management or prescribed fire have been implemented in riparian areas. Although current forest plan standards do not restrict vegetation management in riparian areas, the time and complexity to complete National Environmental Policy Act analysis and associated regulatory consultation for vegetation treatments or prescribed burning in riparian areas has generally limited those actions from being implemented. Forest succession in the absence of disturbance, particularly wildland fire, has resulted in encroachment of conifer species into some riparian areas and meadows. In these particular areas, conifer species have replaced much of the tall woody species, such as willows, cottonwood, and birch. Reintroduction of fire commensurate with natural fire regimes could reestablish tall hardwoods and shrubs as well as help to maintain a mosaic of vegetation species and composition. For example, beavers require deciduous trees or shrubs as a food source as a basic requirement. Their dam building activities can create diversity in stream channel morphology, store water for increased year-round flow, lower water temperatures, raise water tables, dissipate flood energy, and store carbon.

Increasingly, restoration practitioners are using beavers to accomplish stream, wetland, and floodplain restoration (Castro et al. 2018). Beaver populations have declined across much of the Nez Perce-

Clearwater, primarily due to heavy trapping in the 1800s. More recently, decline is due to a combination of factors including reductions in herbaceous and woody vegetation, direct removal of animals, trapping, livestock grazing impacts, roads located in riparian areas, and other human activities. Under the prolonged absence of fire, some riparian areas have converted more towards coniferous tree species and away from the aspen, cottonwood, poplar, and willow species preferred by beavers.

Roads have the potential to affect aquatic ecosystems through several direct and indirect pathways and to modify natural drainage patterns which often lead to accelerated erosion of road surfaces and associated cut and fill slopes. This can lead to increased sediment delivery to streams. Roads can affect stream channels directly if they are located on active floodplains or directly adjacent to stream channels acting as a chronic source of sediment and interrupting floodplain function. If the road impinges on the morphological characteristics of the stream, it can set forth a chain reaction of channel adjustments that can result in accelerated bed and bank erosion, which produces excessive sediment. Roads can also affect floodplains by disconnecting them from the river channel, potentially altering subsurface flows and groundwater contributions to the river. Roads in riparian areas result in a semi-permanent loss of riparian vegetation, which can influence the amount of solar radiation reaching a water body, increase water temperatures, and alter the amount of wood available for recruitment into the stream ecosystem.

Roads can result in changes in channel morphology, especially at road crossing locations. Poorly placed roads can encroach on stream channel and floodplain areas. Many older roads were constructed very close to stream channel areas, often in the floodplain. Often streams were straightened to accommodate road routing. Roads can permanently affect wetlands by interrupting natural flow paths and channelizing water flow through culverts.

System roads generally have notable impact to riparian and wetland conditions and floodplain function on the Nez Perce-Clearwater. Out of the 7,682 miles of Forest Service system roads, 1,600 miles of road or approximately 6,400 acres occur within riparian management zones. Approximately 686 miles of road or 2,700 acres are located within 100 feet of stream channels and wetlands, which equates to approximately 7 percent of the total road system. Some of these road miles are continuous along substantial lengths of a stream channel or are unconnected sections of road that interact with streams only at stream crossings.

Over 60 percent of the Nez Perce-Clearwater's land base is contained within designated wilderness or Idaho Roadless Areas. Approximately 70 percent of river miles in the plan area flow through these areas. It is assumed that natural processes drive riparian and wetland conditions and floodplain function in these areas and that conditions are within the natural range of variation.

Groundwater Dependent Ecosystems

Groundwater and surface water are interconnected and interdependent in almost all ecosystems. Ground water plays significant roles in sustaining the flow, chemistry, and temperature of streams, lakes, springs, and wetlands in many settings, while surface waters provide recharge to ground water in other settings. Groundwater-dependent ecosystems are communities of plants, animals, and other organisms that rely on access to or discharge of groundwater such as springs, fens, seeps, areas of shallow groundwater, cave and karst systems, hyporheic zones, and groundwater-fed lakes, streams, and wetlands. Owing to their unique water and chemical characteristics, groundwater dependent ecosystems often support rare and endemic species, as well as provide critical ecosystem services including water storage, supply and purification. Impacts to the quantity, timing and quality of groundwater discharge to these ecosystems have notable consequences to their persistence and viability.

Peatlands, including fens and fogs, are rare and important. Are uncommon habitats that provide habitat for unique plant and animal communities. These wetlands form where high water tables and permanent saturation slows rates of decomposition and where soils are formed from accumulating partially decayed organic matter. Peatlands generally occur as small, discreet landscape features. Locations and extent of peatlands, as with other groundwater dependent ecosystems, are not well documented. Known occurrences of peatlands exist in some research natural areas and special areas on the Nez Perce-Clearwater, such as the Sing Lee Wetland botanical special area and the wispin'iitpe botanical and historical special area, which includes Packer Meadows.

Groundwater dependent ecosystems contain ecological resources that potentially are highly susceptible to permanent or long-term environmental damage from contaminated or depleted ground water. Ground water extraction or interception by humans modifies the pre-existing hydrologic cycle. It can lower ground water levels and alter the timing, availability, and volume of ground water flow to dependent ecosystems. The largest threats to springs, seeps, and groundwater habitats are those that change water flow, temperature, or water quality. Particular threats to groundwater dependent ecosystems on the Nez Perce-Clearwater include roads that intercept and/or redirect ground water, contamination of water from chemicals and oils on road surfaces, diversion for public water supply, ground disturbance from livestock, diversion for livestock water developments, salting associated with livestock grazing, entrenchment of streams, and modification of forested vegetation that alters groundwater and surface flows or changes microclimates.

Benefits to People and Key Ecosystem Services

Healthy streams, lakes, and rivers benefit Americans in a myriad of ways, from clean drinking water to diverse recreational opportunities. One in five Americans rely on water that comes from National Forest System lands (U.S. Department of Agriculture 2017e). Water from National Forests is valued for many ecological, cultural, economic, and social purposes. Healthy, properly functioning watersheds provide ecosystem services and multiple uses that provide benefits to people either directly or indirectly and contribute to long-term social and economic sustainability.

Water is the basis for many of the recreational and amenity values people seek. Altered flows and reduced water quality could affect forest visitor use and long-term economic sustainability. Adequate flow and water quality are essential to maintaining key fish species and fisheries, which in turn, are sources of many economic, cultural, and spiritual values.

The Forests to Faucets 2.0 assessment identified Hydrologic Unit Code (HUC) 12 watersheds in the United States that are most important to surface drinking water sources (Mack et al. 2021). The assessment also identifies forested areas important to the protection of drinking water and areas where the quantity and quality of drinking water supplies might be threatened by climate change, development, insects and diseases, or wildland fire. Watersheds on the Nez Perce-Clearwater have a moderate importance for the delivery of surface drinking water supplies from waters originating on the Forests (Mack et al. 2021). The assessment also indicated that lands within the Nez Perce-Clearwater have minimal threats to surface water supply from land use changes and moderate to high threats to surface water supply from climate change, insects and disease, and wildfire.

Ecosystem services are broken out into four distinct categories: provisioning, supporting, regulating, and cultural. Provisioning services are products obtained from ecosystems, such as abundant clean water. Supporting services are equivalent to ecosystem functions, such as nutrient cycling. Regulating services are benefits obtained from the regulation of ecosystem processes, such as water filtration and storage; slope stabilization; flood and drought control; delivery of public water, including maintenance of consumptive and non-consumptive water rights; supply of drinking water; and support of municipal watersheds and source water protection areas. Cultural services are nonmaterial benefits obtained from ecosystems, such as adequate flows for sustainable recreation opportunities. For some American Indian tribes, water is considered a culturally significant food used for ceremonies and subsistence needs. These goods and services are essential to the social, environmental, and economic well-being of local communities. The wide array of critical ecosystem services provided by healthy watersheds is frequently undervalued when making land use decisions. Due to the complexity of natural systems and economic precedents, it is difficult to assign a dollar amount to a particular ecosystem service. An assessment completed locally by the Ecosystem Research Group (Ecosystem Research Group 2018) estimated that just the waters in the Clearwater River and tributaries upstream of Orofino yields an estimated value of $168 million per year. This is based on an average annual water flow of 6.4 million acre-feet of water per year for the Clearwater River measured at Orofino and a conservative value of $26.34 per acre-foot.

Water is a key ecosystem service that is provided by the Nez Perce-Clearwater. It is important in the broader landscape and outside the plan area and is likely to be influenced by the proposed Land Management Plan. Figure 34 shows the extent of contribution the water originating from the Nez Perce-Clearwater has on the larger Snake and Columbia River systems, which support many communities in Idaho, Washington, and Oregon (U.S. Department of Agriculture 2020b).

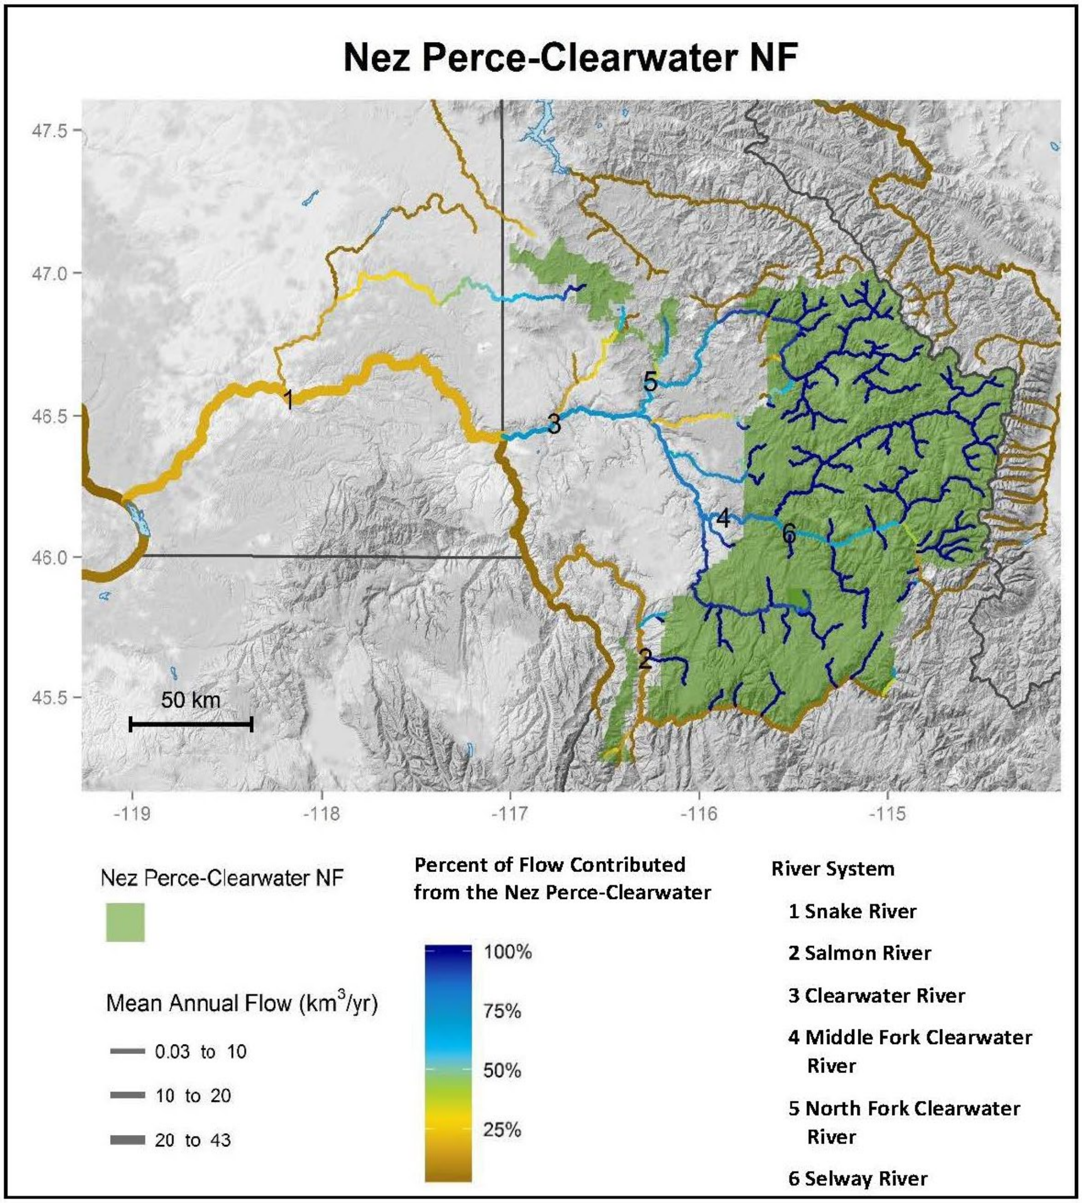

Figure 34. Flow contribution from the planning area to major rivers

Data Source: USDA Forest Service, Rocky Mountain Research Station, Estimating the Contribution of Forests to the Nation's Water Supply (U.S. Department of Agriculture 2020b); https://www.fs.fed.us/rm/value/research_cpl.html.

Water that originates on the Nez Perce-Clearwater provides many important benefits, including public drinking water, municipal water supplies, recreational opportunities, aesthetics, fishing opportunities, water for fish and wildlife, livestock watering, and irrigation. Although no large hydropower facilities exist on the Nez Perce-Clearwater, numerous facilities are located downstream on larger river systems. Additionally, water quality and supply are important for ecological sustainability, which contributes to the many benefits and ecosystem services that people derive from the Nez Perce-Clearwater. See Appendix K for additional information regarding public drinking water, municipal water supply watersheds, source water protection areas, groundwater supply, and water rights.

Groundwater is an important resource in Idaho, and it will likely become more important in the future as the State of Idaho's population and industries grow. Ground water is the source of drinking water for 95 percent of Idaho citizens (State of Idaho Department of Environmental Quality 2018). Idaho uses over 38,000 acre-feet of groundwater per day for domestic use, public water supplies, irrigation, livestock, and industry (Murray 2018). Water generated in the mountains of the Nez Perce-Clearwater is an important source of recharge for downstream aquifers and is an important ecosystem service to local communities. The Nez Perce-Clearwater contains all or portions of the following groundwater flow systems – Palouse River, Hangman Creek, Clearwater Uplands, Clearwater Plateau, Mill Creek, Little Slate Creek, Elk City, and Red River (Graham and Campbell 1981).

Pumping of groundwater can reduce river flows, reduce, or eliminate discharges to wetlands and springs, and influence the sustainability of drinking-water supplies. Due to relatively sparse populations and an extensive amount of wilderness and roadless areas, utilization of Nez Perce-Clearwater groundwater is generally limited. Consumptive groundwater use within the Nez Perce-Clearwater is restricted to special-use permits, Forest Service campgrounds or administrative sites with domestic wells, private in-holdings, and in-forest communities.

There are few natural sources of groundwater contamination. Most threats to groundwater quality are linked directly or indirectly to a variety of human activities. Any type of hazardous material that soaks into the ground has the potential to contaminate ground water resources. Contamination of soils and ground water can be difficult, time-consuming, and expensive to address so it is much easier and cost-effective to protect groundwater than it is to remediate after contamination has occurred. Groundwater can be contaminated by fuel spills from long haul truck accidents, saline runoff from roads and highways, herbicide application, and leaching and seepage from mine spoils and tailing impoundments. Over the past decade, there have been multiple long-haul truck accidents on U.S. Highway 12 along the Lochsa River that have drained thousands of gallons of fuel into the groundwater and river.

Municipal Watersheds

Direction for management of National Forest System watersheds that supply municipal water is provided in 36 CFR 251.9 and Forest Service Manual 2542. The Forest Service is directed to manage National Forest watersheds for multiple uses while recognizing domestic supply needs. Municipalities may apply to the Forest Service for municipal watershed agreements if they desire protective actions or restrictive measures to protect municipal water supplies not specified in the Land Management Plan. Formal written agreements to ensure protection of water supplies may be appropriate when multiple use management fails to meet the needs of a water user. Although there are currently no municipal watershed agreements established for watersheds on the Nez Perce-Clearwater, agreements could be developed in the future.

Forest Service Manual 2542.03 provides guidance to identify watersheds providing the principal source of community water during land management planning. The Nez Perce-Clearwater provides the principal source of community water for the communities of Elk River, Elk City, and Pierce. See Appendix K for additional information regarding municipal water supply.

Source Water Protection Areas

Source water protection areas protect public water systems from contamination in accordance with the 1996 amendments to the Safe Drinking Water Act. Public water systems are defined under the Safe Drinking Water Act as entities that provide "water for human consumption through pipes or other constructed conveyances to at least 15 service connections or serves an average of at least 25 people for at least 60 days a year."

Source water is untreated ground water (aquifers and springs) and surface water (rivers, streams, and lakes) used to supply drinking water for private and domestic wells and public water systems. Groundwater and surface water used for drinking water supplies are often vulnerable to contamination from land use practices and potential contaminant sources within the vicinity of drinking water wells and intakes.

The Nez Perce-Clearwater contains 80,000 acres of source water protection areas; 6,500 acres from groundwater and 73,500 from surface water. Source water protection areas occur within 57 Hydrologic Unit Code (HUC) 12 subwatersheds. See Appendix K for a delineation of source water protection areas by subwatershed.

The Idaho Department of Environmental Quality's Source Water Protection Program provides guidance and approval of source water protection areas within the State of Idaho. The State of Idaho has completed a source water assessment for each of the 41 public water systems derived from the Nez Perce-Clearwater. A source water assessment summarizes the likelihood of individual drinking water sources becoming contaminated and serves as a foundation for public water systems to prepare source water (drinking water) protection plans and implement protection measures.

Source water protection is a voluntary effort a community can implement to help prevent contamination of the source water that supplies its public water system. A Source Water Protection Plan is a written plan a community develops to document its source water protection activities and outlines the management tools the local community plans to use to protect drinking water sources. The following communities utilize water flowing from the Nez Perce-Clearwater and have formalized source water protection plans established with the Idaho Department of Environmental Quality: City of Elk River (Idaho Rural Water Association 2008), Elk City Water and Sewer Association (Idaho Department of Environmental Quality 2017), City of Kamiah (Hummer and City of Kamiah Planning Team 2017), City of Orofino (City of Orofino 2006), City of Lewiston (City of Lewiston and Asotin County Public Utility District 2010), City of Juliaetta (City of Juliaetta 2019), Riverside Independent Water District (Idaho Department of Environmental Quality 2013), City of Kooskia (City of Kooskia 2013), and City of Potlatch (Idaho Rural Water Association 2010).

There are 13 public water systems that have surface water intakes located on Nez Perce-Clearwater land or that have surface water source water protection areas that extend onto Nez Perce-Clearwater lands, as delineated in the source water assessments. These public water systems serve approximately 22,650 people. The communities of Elk River, Elk City, Kamiah, Orofino, Lewiston, Juliaetta, Pierce, and Riverside derive their domestic water supply directly from the surface water originating from within the Nez Perce-Clearwater. Approximately 73,490 acres of the Nez Perce-Clearwater are delineated as source water protection areas for surface water intakes. See Appendix K for more information regarding public water systems.

There are 28 public water systems withdrawing groundwater from wells and springs within Nez Perce-Clearwater land or have groundwater source water protection areas that extend onto Nez Perce-Clearwater lands as delineated in the source water assessments. These public water systems serve approximately 6,240 people. The communities of Grangeville, Kooskia, and Potlatch derive groundwater that drains from Nez Perce-Clearwater land. Approximately 6,440 acres of the Nez Perce-Clearwater are delineated as source water protection areas for groundwater intakes. See Appendix K for more information regarding public water systems.

Watershed Restoration

The aim of the Nez Perce-Clearwater watershed restoration program is to maintain and restore healthy watershed, riparian, wetland, and aquatic ecosystems within the context of broad ownership patterns and in collaboration with partners. Over the past 25 years, restoration work has been completed through partnerships with county, state, and federal agencies; private organizations; and youth education programs. The primary restoration partner on the Nez Perce-Clearwater is the Nez Perce Tribe, which has invested millions of dollars in project areas that cover the Lolo Creek watershed and most of the Middle Fork Clearwater, South Fork Clearwater, Lochsa, and Selway River subbasins.

The watershed restoration program is a multi-million-dollar program that supports approximately 30 permanent positions in county and state agencies, and the Nez Perce Tribe, and provides substantial work to several local contracting businesses. Restoration actions have primarily focused on road decommissioning and culvert upsizing on open roads to pass 100-year flows and allow for aquatic organism passage. Other watershed, riparian, wetland, and aquatic restoration projects have included rehabilitation of abandoned mines, soil decompaction, planting of native vegetation, stabilization of stream banks, fencing of riparian and wetland areas, removal of streamside mine tailings, improving stream habitat, meadow restoration, installing beaver dam analogs, in-stream large wood placement, re-meandering stream channels. These activities have resulted in decreased sediment delivery and improved riparian functions and stream processes.

Restoration is the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Ecological restoration focuses on reestablishing the composition, structure, pattern, and ecological processes necessary to facilitate terrestrial and aquatic ecosystems sustainability, resilience, and health under current and future conditions. Restoration may not necessarily return an ecosystem to its former state, because contemporary constraints and conditions can cause it to develop along an altered trajectory (U.S. Department of Agriculture 2006, Clewell et al. 2005).

Restoration needs on the Nez Perce-Clearwater include, but are not limited to, the following:

- Treating vegetation strategically, managing natural wildfire, and utilizing prescribed fire are needed to alter the structure, pattern, and composition of upland and riparian vegetation to move towards desired conditions, restore fires role on the landscape, and increase resilience;
- Maintaining or improving riparian area conditions, stream habitat, and existing and predicted future stream thermal refugia;
- Decommissioning or relocating system roads on unstable slopes and/or stream adjacent; if not feasible focus on improving roads by hydrologically disconnecting and/or storm proofing;
- Removing or upgrading fish passage barriers that block or restrict access to historically occupied aquatic habitats or restrict connectivity between aquatic habitats;
- Storm proofing and hydrologically disconnecting system roads, including upsizing road stream crossings and road drainage features; Restoring or promoting a diversity of tree and plant species to increase stream shading, provide sources of woody debris, stabilize the soil, and restore fluvial processes;
- Removing, relocating, or mitigating dispersed sites in riparian areas that are causing resource impairment;
- Reconstructing or improving system roads, focusing on roads with chronic sediment delivery to streams or potential future road prism failures;

- Improving trail systems, focusing on trail segments with chronic sediment delivery to streams;
- Improving meadow conditions, including installation of beaver dam analogs, relocation of roads, increased drainage through roads, and reduced conifer encroachment;
- Restoring hydrologic connectivity of floodplains and meadows; and
- Reintroducing or supplementing beaver into suitable habitats within their former range.

Restoration actions that are intended to improve water quality can often result in short-term adverse effects to water quality, specifically if the implementing actions occur within or adjacent to a water body. Short-term adverse effects are anticipated and considered acceptable when activities provide long-term protection or improvement of water quality and riparian and wetland condition and function.

Environmental Consequences

This section describes the effects of forestwide management as outlined in the Land Management Plan on water resources. The Land Management Plan provides a programmatic framework that guides site-specific actions but does not authorize, fund, or carry out any project or activity. Because the Land Management Plan does not authorize or mandate any site-specific projects or activities, including ground-disturbing actions, there can be no direct effects. However, there may be implications or longer-term environmental consequences of managing the Nez Perce-Clearwater under this programmatic framework.

The 2012 Planning Rule requires that National Forests provide for social, economic, and ecological sustainability within Forest Service authority and consistent with the inherent capability of the plan area (36 CFR 219.8). Sustainability is defined as the capability to meet the needs of the present generation without compromising the ability of future generations to meet their needs. Watersheds with functioning watershed condition and good water quality support ecological sustainability. Water resources that provide ecosystem services or benefits to people and surrounding communities support economic and social sustainability.

The Nation's forests and grasslands that provide clean and available water are a fundamental part of the American landscape and legacy that the Forest Service holds in trust for future and present generations. One of the 2022-2026 U.S. Department of Agriculture Strategic Plan objectives is to restore, protect, and conserve watersheds to ensure clean, abundant, and continuous provision of water resources (U.S. Department of Agriculture 2022a).

Effects Common to All Alternatives

The potential impacts from climate change to water resources would be the same for all alternatives. Regional climate change scenarios project a significant decline in snowpack in the coming decades, with more winter precipitation falling as rain (Halofsky, Peterson, et al. 2018a, b). This reduction in peak snow accumulation will have significant implications for regional hydrology, including more runoff in winter, earlier peak flows in spring, reduced storage capacity associated with snowpack, and declining summer flows (Clark and Harris 2011, Luce and Holden 2009, Luce et al. 2014, Luce et al. 2012, Luce 2018). The increased magnitude of peak streamflows have the potential to damage roads near perennial streams, ranging from minor erosion to extensive damage, thus affecting public safety, access for resource management, water quality, and aquatic habitat. Bridges, campgrounds, and national forest facilities near streams and floodplains will be especially vulnerable, potentially reducing access by the public (Halofsky, Peterson, et al. 2018a, b).

Increasing temperatures; changing precipitation patterns; and more frequent, intense, and unpredictable extreme weather conditions caused by climate change are exacerbating existing risks. In addition to affecting the amount of available water, climate change is also expected to reduce overall water quality, due to higher summer water temperatures and changes in the timing, intensity and duration of precipitation events. A possible increase in frequency and intensity of rainfall during fall and winter months could produce more overall pollution and sedimentation entering waterways, as well as an increased possibility of flooding in winter and early spring (Clark and Harris 2011). Decreased snowpack in combination with higher air temperature could increase stream temperatures (Halofsky, Peterson, et al. 2018a).Decreasing snowpack and declining summer flows will alter timing and availability of water supply, affecting agricultural, municipal, and public uses in and downstream from national forests. Declining summer water flows may result in some communities experiencing summer water shortages (Halofsky, Peterson, et al. 2018a, b). Water flows could affect water rights and beneficial uses. Most of the streams in the western subregion depend on snowmelt for runoff and snowpack changes strongly dictate streamflow responses (Halofsky, Peterson, et al. 2018a, b). Changes in the timing of streamflow related to changing snowmelt are already observed and will continue, reducing the supply of water for many competing demands and causing far-reaching ecological and socioeconomic consequences (Mote et al. 2014).

The 2012 Planning Rule requires a plan to include plan components to maintain or restore structure, function, composition, and connectivity of terrestrial and aquatic ecosystems and watersheds, taking into account stressors, such as climate change (36 CFR 219.8(a)). Although the No Action does not contain explicit information on climate change, the 1987 Forest Plans provide management direction that promotes healthy forest and watershed conditions. Under the Action Alternatives, the Land Management Plan includes many desired conditions that promote resilient physical and biological ecosystems. Resilient systems are better able to adapt to changing climates. Desired condition FW-DC-WTR-01 describes National Forest System lands that provide the distribution, diversity, and complexity of watershed and landscape-scale features, including natural disturbance regimes and the aquatic and riparian ecosystems to which species, populations, and communities are uniquely adapted. Watersheds and associated aquatic ecosystems retain their inherent resilience to respond and adjust to disturbances, including climate change, without long-term, adverse changes to their physical or biological integrity. Primary adaptation strategies to address changing hydrology due to climate change in the Northern Rockies (Halofsky, Peterson, et al. 2018a, b) include restoring the function of watersheds, connecting floodplains, reducing drainage efficiency, maximizing valley storage, and reducing hazardous fuels. Adaptation tactics include adding wood to streams, restoring beaver populations, modifying livestock management, and reducing surface fuels and forest stand densities. Primary strategies for infrastructure include increasing the resilience of stream crossings, culverts, and bridges to higher peak flows and facilitating response to higher peakflows by reducing the road system and disconnecting roads from streams. Further discussion of climate change effects can be found within the Climate Change and Forest Carbon section. See also Appendix G for specific examples of potential climate adaptation strategies that were used in the development of forest plan components to help sustain the fundamental ecological functioning of water resources.

Effects of the No Action Alternative

Under the No Action Alternative, the 1987 Nez Perce National Forest Plan (U.S. Department of Agriculture 1987b) and 1987 Clearwater National Forest Plan (U.S. Department of Agriculture 1987a) would continue to provide direction for the combined Nez Perce-Clearwater unless modified by a forest plan amendment. Analysis of a no action alternative is a requirement of the National Environmental Policy Act.

The Nez Perce and Clearwater 1987 Forest Plans provide direction for the protection and management of water quality and quantity, watershed processes, and riparian and channel function. In 1995, the Chief of the Forest Service amended the Nez Perce National Forest Plan (Amendment 20) and Clearwater National Forest Plan (Amendment 10) to implement PACFISH for managing anadromous fish-producing watersheds on National Forest lands. The amendment to the Clearwater Forest Plan as included the addition of INFISH guidance. PACFISH and INFISH were designed to provide interim aquatic and riparian management guidance, halt further degradation, and begin recovery aquatic ecosystems. While these strategies were initially intended to be interim guidance, they have now been in place on the Nez Perce-Clearwater for over 25 years. They established and defined interim riparian habitat conservation areas, prescribed specific standards and guidelines that limited activities within the riparian habitat conservation areas, and established riparian management objectives. The 1995 forest plan amendments interim direction intended to remain in effect until forest plans are amended or revised. See the Aquatic Ecosystems and Fisheries section, particularly the Policy and Affected Environment pieces, for more information regarding PACFISH and INFISH amendments to the Nez Perce and Clearwater forest plans.

Both the Nez Perce and Clearwater forest plans, as amended by PACFISH and INFISH, include goals and standards for the protection of water quality, water quantity, and aquatic habitat during management activities and include directions to implement best management practices. Since the Nez Perce and Clearwater National Forests administratively combined in 2012, it has been difficult to provide consistent water management administration across the combined Nez Perce-Clearwater because the direction from the two forest plans differ. This inconsistency mainly impacts forest management planning and implementation.

Watershed Condition

Under the existing 1987 Forest Plans, both Forests have been actively pursuing restoration work to meet forest plan fish and water quality objectives. Restoration has resulted in decreased sediment delivery and improved riparian functions and stream processes. With the addition of PACFISH and INFISH direction, interim riparian habitat conservation areas were established and specific standards and guidelines that limited activities within the riparian habitat conservation areas were prescribed. Passive restoration in riparian habitat conservation areas since 1995 have also improved overall watershed condition. Both active and passive restoration would continue under the No Action Alternative as long as the Nez Perce-Clearwater continues to prioritize watershed restoration and emphasize partnership opportunities. The national Watershed Condition Framework program (U.S. Department of Agriculture 2011d) established in 2011 provides a method for classifying watershed condition and offers broad guidance to help national forests prioritize integrated, subwatershed scale restoration actions. This program would continue to be used under the No Action Alternative.

There would continue to be localized improvements to watershed, soil, riparian, and aquatic habitat conditions as projects are implemented but watershed-scale improvements may occur slowly given current and anticipated funding levels. Under the No Action Alternative, location of watershed restoration projects would more than likely, be prioritized and directed by more commodity-based resource projects, such as timber harvest and integrated vegetation restoration projects, which has been the case over the last decade.

Designated wilderness and Idaho Roadless Areas cover just over 50 percent of the Nez Perce-Clearwater and natural ecological processes and disturbances dominate. The Idaho Roadless Rule designated approximately 1,500,000 acres to be managed as roadless under specific themes. This reduced timber harvest and road construction potential relative to the 1987 estimated levels. Watersheds in these areas are in good condition and are functioning within the natural range of variation.

In the more managed portion of the Nez Perce-Clearwater, legacy effects from past livestock grazing; recreation; road and trail construction, maintenance, and use; timber harvest and associated activities; fire exclusion; mining; and other human-caused disturbances continue to affect watershed health. Generally, under the direction of the 1987 Nez Perce and the Clearwater Forest Land Management Plans, the intensity and risks associated with management actions and human-induced disturbances have been reduced when compared to conditions prior to the 1987 Plans, especially with the inclusion of the PACFISH and INFISH amendments. Watershed conditions would be maintained or continue to improve, as a reflection of the adherence to PACFISH and INFISH standards, use of best management practices, and implementation of watershed restoration activities.

Water Quality

Both the Nez Perce and Clearwater forest plans, as amended, also have standards that require management activities to meet or exceed State of Idaho water quality standards, protect beneficial uses, and provide for public water supply (Clearwater Goal 10a, Standard 8b and 8m, and Amendment 10, Standards 1 and 2; Nez Perce Goals 3 and 21, Standard 1, and Amendment 20, Standards 1 and 2).

Both plans established fishery and water quality objectives and include standards to meet those objectives (Clearwater Standards 8d and 8e; Nez Perce Standard 8). Watershed systems were assigned water quality objectives in Appendix K of the Clearwater National Forest Plan and prescription watersheds were assigned fish and water quality objectives in Appendix A of the Nez Perce Forest Plan. These objectives provide management direction in terms of the maximum estimated increase in sediment over baseline conditions that can be approached or equaled for a specific number of years per decade. Watersheds not meeting fish and water quality objectives in 1987 were identified and associated upward trend requirements were imposed, which allowed timber management to occur concurrent with watershed improvement efforts, as long as a positive, upward trend in habitat carrying capacity was indicated (Clearwater Standard 8h, Nez Perce Standard 8). The 1993 Stipulation for Dismissal for the Clearwater Forest Plan litigation (1993)mandates that any activity in a watershed not meeting water quality objectives outlined in Appendix K yield no net increase of sediment during the project. Appendix A of the Nez Perce Forest Plan also assigned entry frequency guidelines for each of the prescription watersheds, limiting the number of timber harvest projects allowed per decade. Appendix K of the Clearwater Forest Plan set an allowable number of years in 30 years that the sediment yield threshold could be exceeded.

The fishery and water quality objectives in the 1987 Forest Plans were tied to particular sediment delivery prediction models, utilizing information, formulas, and coefficients outlined in the R1/R4 Guide for Predicting Sediment Yields (Cline et al. 1981). The WATBAL model was used on the Clearwater National Forest and the NEZSED model was used on the Nez Perce National Forest. Both of the original model platforms the models were built on no longer exist. The NEZSED model now is used in an excel spreadsheet format. As R1/R4 Guide for Predicting Sediment Yields was published in 1981, some of the assumptions were based on forest practices related to harvest and road construction that occurred in the 1960s and 1970s. Since then, there have been advances in technology, PACFISH and INFISH amendments to the forest plans, development and implementation of best management practices, and updates to contract provisions.

More research and improvement in sediment modeling technology has occurred since the 1987 plans were developed (Hyde et al. 2006, Nelson et al. 2019, Black et al. 2012). Since the mid-2000s, the Nez Perce-Clearwater has also been utilizing the Water Erosion Prediction Project (WEPP) model and Geomorphic Road Analysis and Inventory Package (GRAIP) and GRAIP-Lite models developed by the U. S. Forest Service Rocky Mountain Research Station to aid in erosion and sediment delivery evaluations.

Implementation of best management practices would continue as directed in both forest plans (Clearwater Objective 9d, Standard 8c and 8k; Nez Perce Standard 1). Best management practices are outlined in the National Core Best Management Practices Technical Guide (U.S. Department of Agriculture 2012b), the Soil and Water Conservation Practices handbook (U.S. Department of Agriculture 1988b), Rules Pertaining to the Idaho Forest Practices Act (Idaho Department of Lands 2022b), Stream Channel Alteration Rules (Idaho Department of Environmental Quality 2005), and Dredge and Placer Mining Operations in Idaho (Idaho Department of Lands 1992).

Water Quantity

Both the Nez Perce and Clearwater forest plans include standards to maintain water quantity and provide guidance for proposed activities that have a potential to significantly alter water flow, quantity, timing, or flow duration (Clearwater Objective 9a, Standards 8a and 8l, Amendment 10, Goals 3 and 4; Nez Perce Goal 20, Objective 2, Standards 5, 6 and 7, and Amendment 20, Goals 3 and 4). The Nez Perce and Clearwater forest plans do not include guidance regarding climate change or offer adaptation strategies.

Both forest plans require a watershed cumulative effects feasibility analysis for projects involving significant vegetation removal prior to including the projects on the implementation schedules to ensure that the project, considered with other activities, will not increase water yields or sediment beyond acceptable limits. Both plans also require that the analysis identifies any opportunities for mitigating adverse effects on water-related beneficial uses, including capital investments for fish habitat or watershed improvement (Clearwater Standard 8g(4); Nez Perce Standard 4).

Riparian Areas, Wetlands, and Floodplain Function

Both the Nez Perce and Clearwater forest plans include management direction to maintain or restore riparian areas (Clearwater Standard 8a, Amendment 10, Goals 5 and 6; Nez Perce Goal 22; Amendment 20, Goals 5 and 6). Both forest plans, as amended by PACFISH and INFISH, delineated and established interim riparian habitat conservation areas widths and assigned standards and guidelines to particular management activities to limit impacts to riparian areas and better attain riparian management objectives. See the Aquatic Ecosystems and Fisheries section for more information regarding PACFISH and INFISH amendments to the Nez Perce and Clearwater forest plans.

Riparian habitat conservation areas are considered their own Management Area in both the Nez Perce and Clearwater Forest Plans. Forestwide goals and direction in the 1987 plans address water quality, stream channel integrity, diversity of plant communities, riparian-dependent wildlife, and other features associated with aquatic and riparian areas that provide protection for the riparian-associated resources and values. They include direction allowing no management in riparian areas that would cause detrimental changes in water temperature or chemical composition, blockages of water courses, or deposits of sediment that seriously and adversely affect streams or fish.

Riparian habitat conservation areas (RHCA) are classified as not suitable for timber production. Timber harvest is allowable within riparian habitat conservation areas if conducted to achieve objectives for the stream and riparian habitat conservation areas. Prescribed fire is also prohibited in RHCAs unless designed to improve riparian condition. See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section for specific PACFISH standards under the No Action Alternative. In practice, timber harvest and prescribed burning activities within RHCA's have not been conducted, despite being permissible under PACFISH. The time and complexity to complete NEPA analysis and associated regulatory consultation for vegetation treatments or prescribed burning in riparian areas has generally limited those actions from being implemented. The No Action Alternative assumes that the majority of projects would continue to not propose treatments within RHCAs.

Municipal Water Supplies and Source Water Protection Areas

Management under both the Nez Perce and Clearwater forest plans require protections for municipal water supplies and source water protection areas (Clearwater Goal 1, Standards 8k and 8m; Nez Perce Goal 21, Management Area 22 and 23). The Nez Perce forest plan included designated management areas for Wall Creek Municipal Watershed and Elk Creek Municipal Watershed to ensure that the Idaho water quality standards for community public supply water uses are met and beneficial uses are protected. Management Area 22 consists of the Wall Creek Municipal Watershed which provided water for domestic use to the town of Clearwater, Idaho. The instream water reservoir and intake is no longer active and the city obtains its water from groundwater wells (Public Water System # ID2250011). The Wall Creek Municipal Watershed Management Plan, last updated in 1990, is no longer valid. Management Area 23 consists of the National Forest portion of the Elk Creek Municipal Watershed which provides water for domestic use to the town of Elk City, Idaho. There is no official Municipal Watershed Management Plan on record between Elk City and the Nez Perce National Forest.

Under the No Action Alternative, water from the Nez Perce-Clearwater would continue to provide ecosystem services to downstream communities.

Effects Common to Action Alternatives

The 2012 Planning Rule requires forest plans to include plan components that emphasize the maintenance or improvement of water quality (36 CFR 219.8(a)(2)(iii)) and promote the maintenance or restoration of water resources in the plan area, including lakes, streams, and wetlands; ground water; public water supplies; source water protection areas; and other sources of drinking water; including guidance to prevent or mitigate detrimental changes in water quantity, quality, and availability (36 CFR 219.8(a)(2)(iv)).

Desired conditions in the Land Management Plan provide a vision of the future landscape and serve to focus management attention by describing the specific desired ecological characteristics of the watersheds within the plan area towards which management of the land and resources would be directed. Standards and guidelines are constraint on projects, established to help achieve or maintain the desired conditions, to avoid or mitigate undesirable effects, or to meet applicable legal requirements. Because desired conditions, standards, and guidelines for water and aquatic resources do not vary between Action Alternatives, any differences in the indirect effects to water resources would be based on the variation of the aquatic ecosystems objectives and the projected amounts of objectives for other resources.

The effects analysis evaluates the relative ability of the Action Alternatives to affect watershed conditions; water quality; water quantity; and riparian areas, wetlands, and floodplain function. Many Forest Service management activities have the potential to adversely affect watershed and water resources to some degree, particularly those activities that disturb soil and ground cover in close proximity to water bodies. The goals, desired conditions, standards, and guidelines within the Aquatic Ecosystems section of the Land Management Plan are consistent across all Action Alternatives. Additionally, the Land Management Plan includes a monitoring plan that would track the effectiveness of implementing the Land Management Plan and a management approaches section that offers possible strategies the Nez Perce-Clearwater could undertake to maintain or make progress towards achieving the desired conditions described in the Land Management Plan.

The analysis primarily focuses on management activities that occur in the more managed portion of the Nez Perce-Clearwater, which is delineated as Management Area 3 and covers 1,240,340 acres under the Preferred Alternative; approximately 30 percent of the Nez Perce-Clearwater. Management Area 3 is described as the “front country” and broadly consists of the areas with roads, trails, developed recreation sites, and structures, as well as evidence of past and ongoing activities designed to actively manage the area. The rest of the Nez Perce-Clearwater is split into Management Areas 1 and 2 lands where more natural ecological and disturbance processes occur and where water resources are generally considered to be within the natural range of variation. Management Area 1, consisting of approximately 30 percent of Nez Perce-Clearwater acres for the Preferred Alternative, contains designated wilderness, designated wild and scenic rivers, and National Historic Landmark areas. Management Area 2 encompasses approximately 37 percent of Nez Perce-Clearwater acres for the Preferred Alternative, and includes lands within Idaho Roadless Areas, recommended wilderness areas, eligible and suitable wild and scenic rivers, geographic areas, special areas, and proposed and designated research natural areas.

Watershed Condition

The 2012 Planning Rule requires Land Management Plans to include plan components to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity (36 CFR 219.8(a)(1)).

The desired conditions for watersheds is that National Forest System lands provide the distribution, diversity, and complexity of watershed and landscape-scale features, including natural disturbance regimes and the aquatic and riparian ecosystems to which species, populations, and communities are uniquely adapted. Watersheds and associated aquatic ecosystems retain their inherent resilience to respond and adjust to disturbances, including climate change, without long-term, adverse changes to their physical or biological integrity (FW-DC-WTR-01).

The watershed condition indicator addresses overall health and resiliency of subwatersheds (HUC12)as classified through the Watershed Condition Framework program. . Existing watershed conditions vary across the Nez Perce-Clearwater, ranging from those unaffected by direct human disturbance to those exhibiting various degrees of modification and impairment. In 2011, the Nez Perce-Clearwater completed the Watershed Condition Classification for 220 subwatersheds. In summary, 140 subwatersheds were rated as Functioning Properly, 73 were rated as Functioning at Risk, and 7 were rated as having Impaired Function. A watershed that is functioning properly is resilient and able to recover to the desired condition when altered by natural disturbances or land management activities (Yount and Niemi 1990).

To facilitate moving watershed condition towards the desired condition, objective FW-OBJ-WTR-01 aims to complete the actions identified in watershed restoration action plans for 10 to 20 priority watersheds, depending on alternative (Table 118), as identified under the Watershed Condition Framework process every 15 years. Objective FW-OBJ-WTR-05 aims to improve soil and watershed conditions on 2,500 to 5,300 acres, depending on alternative (Table 118), every 5 years, emphasizing actions in priority watersheds and Conservation Watershed Network watersheds. This includes non-system road decommissioning.

Overall, the Land Management Plan is intended to provide an integrated approach to promoting the restoration of natural landscapes and natural processes. Instead of focusing on local scale concerns, the focus would be to move the entire landscape toward a more natural functioning system within the natural range of variation. The plan components for most natural resource areas are intended to maintain or increase ecological integrity and resiliency.

Priority watersheds

The 2012 Planning Rule requires Land Management Plans to identify watershed(s) that are a priority for maintenance or restoration (36 CFR 219.7(f)(1)(i)). Identification of priority watersheds is done to focus effort on the integrated restoration of watershed conditions in these areas. The Forest Service National

Watershed Condition Framework must be used in all plan revisions for identifying priority watersheds. The plan should include plan components that address conditions in priority watersheds. The 2012 Planning Rule Directives require watersheds that are a priority for restoration and maintenance be identified in Land Management Plans. The Nez Perce-Clearwater Land Management Plan identifies Upper Elk Creek (Hydrologic Unit Code [HUC] 12 #170603080701), Upper Clear Creek (HUC12 #170603040102), Upper Little Slate Creek (HUC12 #170602090301), Musselshell Creek (HUC12 # 170603060202), and Lower Crooked River (HUC12 # 170603050302) as a priority for maintenance or restoration.

By design, Watershed Condition Framework priority watersheds are not intended to be permanent designations—when all needed work is completed, a new Watershed Condition Framework priority watershed is to be identified. Priority areas for potential restoration activities could change quickly in response to disturbance events, such as wildfire, landslides, severe flooding, or rapid expansion of invasive species. Therefore, the 2012 Planning Rule includes priority watersheds as other plan content so that an administrative change could be used to quickly respond to changes in priority.

Under all Action Alternatives, essential project implementation would continue in Upper Elk Creek, Upper Clear Creek, Upper Little Slate Creek, Musselshell Creek, and Lower Crooked River as outlined in the watershed restoration action plans. Future priority watersheds would be determined throughout the life of the Land Management Plan. Priority watersheds are selected by a Forest or area responsible official after analysis and evaluation using a multi-functional interdisciplinary approach. The participation of partners in the priority selection process is expected and highly encouraged. The 2012 Planning Rule and the planning directives require the responsible official to reach out to local, state, tribal, other federal agencies and interest groups when identifying priority watersheds (Forest Service Handbook 1909.12, section 22.31).

The use of the Watershed Condition Framework process and the rate of priority watersheds moved to an improved watershed condition class would increase under all Action Alternatives when compared to the No Action Alternative (Table 118). The Preferred Alternative proposes to complete the actions identified in watershed restoration action plans for 15 priority watersheds, as identified under the Watershed Condition Framework process every 15 years (FW-OBJ-WTR-01).

Water Quality

The 2012 Planning Rule requires Land Management Plans to include plan components, including standards or guidelines, to maintain or restore water quality (36 CFR 219.8(a)(2)(iii)) and include plan components ensure implementation of national best management practices for water quality (36 CFR 219.8(a)(4)).

The water quality indicator addresses the expressed alteration of physical, chemical, and biological components of water quality. It is measured qualitatively by evaluating potential changes in sediment delivery, stream water temperature, and contaminates; as well as potential changes to the amount of streams not meeting beneficial uses and/or amount of streams classified as water quality impaired.

The desired condition for waterbodies on the Nez Perce-Clearwater is that water quality, including groundwater, meets or exceeds applicable state water quality standards, fully supports designated beneficial uses, and is of sufficient quality to support surrounding communities, municipal water supplies, and natural resources. The Forest has no documented lands or areas that are delivering water, sediment, nutrients, and/or chemical pollutants that would result in conditions that violate the State of Idaho's water quality standards (FW-DC-WTR-05). The Land Management Plan also contains desired conditions for maintaining or improving water quality associated with peatlands, including fens and bogs (FW-DC-TE-03); biophysical features, such as such as caves, karst, and rock cavities (FW-DC-CAVE-03); and hot springs (FW-DC-TT-04).

Standards and guidelines to help achieve or maintain the desired conditions for water quality, to avoid or mitigate undesirable effects, or to meet applicable legal requirements are included in the Land Management Plan. They would limit water contamination from fuel spills (FW-STD-WTR-03, FW-STD-RMZ-02); use of herbicides, pesticides, and other chemicals in riparian management zones (FW-STD-RMZ-03, FW-GDL-RMZ-08); aerial spray of chemical retardant, foam, or other fire chemicals (FW-GDL-RMZ-04); application of dust abatement chemicals (FW-STD-ARINF-02); mining activities (FW-STD-AREM-02, FW-GDL-AREM-03); solid and sanitary waste facilities (FW-GDL-ARREC-01); new facilities or infrastructure in floodplains (FW-GDL-ARREC-02); and groundwater use developments (FW-GDL-WTR-05).

Appendix 4 of the Land Management Plan offers a possible management approach for improving water quality, which includes building and maintaining partnerships to fund and implement projects that result in improved water quality (FW-GL-WTR-02).

Sediment was a primary cause for streams on the Nez Perce-Clearwater to not meet beneficial uses and be listed as impaired by the Idaho Department of Environmental Quality. The desired condition for sediment regimes on the Nez Perce-Clearwater is that sediment delivery to streams is of the types, quantities, and rates that support the natural instream sediment transport and storage rates and instream sediment substrate composition (FW-DC-WTR-06). To help watersheds trend toward desired conditions FW-DC-WTR-05 and FW-DC-WTR-06, standard FW-STD-WTR-06 requires management activities in watersheds with approved total maximum daily loads to be designed to comply with the total maximum daily load allocations following project implementation. Standard FW-STD-WTR-04 requires projects to restore or not retard attainment of desired condition if aquatic and riparian desired conditions are not being achieved.

Notable sources of sediment is road construction, reconstruction, maintenance, and use. More sediment is contributed to streams from roads and road construction than any other land management activity (Potyondy and Geier 2011). Desired conditions for roads are that the transportation system has minimal impacts on aquatic and riparian conditions through reduced hydrologic connectivity of roads to streams, lower sediment delivery to streams, reduced road impact to floodplains, and improved aquatic organism passage, where transportation infrastructure affects these features (FW-DC-ARINF-01); that the transportation network is resilient to the effects of climate change, including the ability to accommodate increased runoff and peak flows that may exceed historic streamflow events (FW-DC-ARINF-02); and that roads in the Conservation Watershed Network present minimal risk to aquatic resources (FW-DC-CWN-03). Desired conditions for trails are that trails have minimal impacts on aquatic resources (FW-DC-ARREC-01).

To move towards these desired conditions, objective FW-OBJ-INF-01 aims to complete 600 miles of road work under the Preferred Alternative, such as reconstruction; re-routing; road improvements; decommissioning; or placing roads in intermittent stored service, every 5 years. Priorities shall include reducing effects on desired aquatic and riparian conditions from chronic sediment delivery or potential future road prism failures, including previously decommissioned roads where drainage features have failed. Objective FW-OBJ-INF-02 aims to annually maintain 1,400 miles of operational maintenance level two through five roads under the Preferred Alternative (Table 118). Objective FW-OBJ-CWN-02 proposes to stormproof 10 to 20 percent of roads in Conservation Watershed Network (CWN) watersheds every 5 years, depending on alternative Table 118. The Preferred Alternative aims to stormproof 15 percent every 5 years. There are approximately 3,900 miles of system road within CWNs. Stormproofing 15 percent of those roads would equate to treating approximately 585 miles of road every five years. Additionally, objectives for trail system management aim to annually maintain to standard a minimum of 30 percent of National Forest System trail miles (FW-OBJ-REC-01) and reduce deferred maintenance of trails by five percent, every five years (FW-OBJ-REC-02).

Numerous standards and guidelines are proposed to limit the amount of sediment delivery or alteration of hydrologic flow regime from roads and trails, including limits on sidecasting of road material or snow (FW-STD-ARINF-03, FW-GDL-ARINF-07); routing road drainage away from streams and unstable slopes (FW-GDL-ARINF-09, FW-GDL-ARINF-02); requiring upgrading or removal of stream crossings (FW-STD-ARINF-04, FW-GDL-ARINF-03, FW-GDL-ARINF-05, FW-GDL-ARINF-11, FW-GDL-ARREC-03); avoiding high mass wasting potential areas and wetland areas (FW-GDL-ARINF-04, FW-GDL-ARINF-08, FW-GDL-ARREC-04); and hardening of stream crossings (FW-GDL-ARINF-06, FW-GDL-ARREC-06).

The Land Management Plan also includes standards and guidelines to limit the amount of sediment delivery to streams from the management of other resource areas, including hydrologically disconnecting roads, skid trails, temporary roads, airstrips, and trails (FW-GDL-ARINF-01, FW-GDL-ARREC-05); hardening livestock trail stream crossings and approaches (FW-GDL-GR-02); avoiding construction of new road, temporary road, trail, and landings in riparian management zones (FW-GDL-RMZ-01); limiting ground disturbing activities in riparian management zones from harvest activities (FW-GDL-RMZ-02, FW-GDL-RMZ-03), fire suppression activities (FW-GDL-RMZ-05, FW-GDL-RMZ-06), and saleable sand and gravel extraction (FW-GDL-RMZ-09).

Restoration actions that are intended to improve water quality can result in short-term adverse effects to water quality, specifically if the implementing actions occur within a water body. Short-term adverse effects are anticipated and considered acceptable when activities provide long-term protection or improvement of water quality and riparian and wetland condition and function. These impacts can only be assessed at the site-specific level and would vary depending on type of restoration treatment, current condition of the resource, and characteristics of the area being restored. Changes in water quality may be allowed without an antidegradation review by the Idaho Department of Environmental Quality where determined necessary to secure long-term water quality improvement through restoration projects designed to trend toward natural characteristics and associated uses to a water body where those characteristics and uses have been lost or diminished. Restoration projects would be required to include best management practices during implementation (FW-STD-WTR-02).

Best Management Practices for Water Quality

Best management practices (BMPs) for water quality are methods, measures, or practices used to meet nonpoint source control needs as directed by the Clean Water Act. BMPs can be applied before, during, and after pollution-producing activities to reduce or eliminate the introduction of pollutants into receiving waters (36 CFR 219.19).

The National Best Management Practices Program is guided by the land management planning regulation 36 CFR 219.8 (a)(4), which requires the Chief of the Forest Service to establish requirements for National BMPs for water quality in the Forest Service Directive System. These requirements, and associated program direction, are outlined in Forest Service Handbook 2509.19, Chapter 10 National Core Best Management Practices and Forest Service Manual 2500, Chapter 30, Section 2532 Water Quality Management.

The National Core Best Management Practices Technical Guide (U.S. Department of Agriculture 2012b) provides a standard set of core BMPs and a consistent means to track and document the use and effectiveness of BMPs on National Forest System lands. Appendix K further describes federal and State of Idaho best management practices direction.

The Land Management Plan ensures implementation of national BMPs for water quality (36 CFR 219.8 (a)(4)) through standard FW-STD-WTR-02, which requires project-specific BMPs, including both federal and state BMPs, to be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet soil and watershed desired conditions, and to protect beneficial uses.

Water Quantity

The 2012 Planning Rule requires Land Management Plans to include plan components to maintain or restore water resources in the plan area, including lakes, streams, and wetlands; ground water; public water supplies; source water protection areas; and other sources of drinking water, including guidance to prevent or mitigate detrimental changes in water quantity, quality, and availability (36 CFR 219.8(a)(2)(iv)).

The water quantity indicator addresses changes to the natural flow regime with respect to the magnitude, duration, or timing of the natural streamflow hydrograph. It is measured qualitatively by potential changes in forested vegetation openings; hydrologic connectivity of roads to streams, and consumption of public water supply.

The desired conditions for maintaining or improving the hydrologic flow regime are:

- Spatial connectivity exists within or between watersheds. Lateral, longitudinal, and drainage network connections include floodplains, wetlands, upslope areas, headwater tributaries, and intact habitat refugia. These network connections provide chemically and physically unobstructed routes to areas critical for fulfilling life history requirements of aquatic, riparian-associated, and many upland species of plants and animals. (FW-DC-WTR-02)
- Instream flows are sufficient to create and sustain riparian, aquatic, and wetland habitats and to retain patterns of sediment, nutrient, and wood routing. The timing, magnitude, duration, and spatial distribution of peak, high, and low flows are retained. Stream flow regimes maintain riparian ecosystems and natural channel and floodplain dimensions. (FW-DC-WTR-07)
- Groundwater dependent ecosystems, including peatlands, bogs, fens, wetlands, seeps, springs, riparian areas, groundwater-fed streams and lakes, and groundwater aquifers, persist in size and seasonal and annual timing and exhibit water table elevations within the natural range of variability. Surface and groundwater flows provide late-season stream flows, cold water temperatures, and sustain the function of surface and subsurface aquatic ecosystems. (FW-DC-WTR-08)
- The transportation network is resilient to the effects of climate change, including the ability to accommodate increased runoff and peak flows that may exceed historic streamflow events. (FW-DC-ARINF-02)

To maintain quality and quantity of water flows to, within, or between groundwater dependent ecosystems guideline FW-GDL-WTR-05 requires that new or reconstructed groundwater use developments, such as recreation and administrative sites, drinking water wells, or wastewater facilities, should not be developed in riparian management zones (unless no alternatives exist); should not measurably lower river flows, lake levels, or flows to wetlands or springs; and should not discharge pollutants directly to surface water or groundwater unless covered by a National Pollutant Discharge Elimination System permit.

Roads, depending on density and location, can affect near-surface lateral flow pathways and watershed drainage density, which can alter timing and magnitude of streamflow (Wemple and Jones 2003). To help achieve or maintain the desired conditions for hydrologic flow regimes and to avoid or mitigate undesirable effects standard FW-STD-ARINF-07 requires that when constructing or reconstructing roads in the Conservation Watershed Network and Hydrologic Unit Code (HUC) 12 subwatersheds with Endangered Species Act critical habitat or listed aquatic species, projects shall result in a net decrease in the hydrologic connectivity of the road system and stream channel network unless no further decreases are needed to meet desired conditions for Water and Aquatic Resources or Conservation Watershed Network. Appendix 4 of the Land Management Plan offers a possible management approach that includes methods for decreasing the hydrologic connectivity of the road system. Standard FW-STD-ARINF-04 specifies that new, replacement, and reconstructed stream crossing sites, such as culverts, bridges, and other permanent stream crossings, accommodate at least the 100-year flow, including associated bedload and debris. Guideline FW-GDL-ARINF-10 requires transportation infrastructure to be designed to maintain natural hydrologic flow paths, including surface and subsurface flow, to the extent practical. For example, streams and seeps upslope from roads should have cross-drains or relief culverts with sufficient capacity to ensure water is not routed down ditches.

Altering the amount or distribution of vegetation can affect water quantity and ultimately alter stream channel conditions. In general, removal of the forest canopy increases streamflow for the first few years, but the magnitude, timing, and duration of the response varies considerably among ecosystems. The Forestlands desired conditions emphasize landscape and within-patch patterns that reflect historic fire regimes, which would include increasing amounts and size of early seral openings.

Standard FW-STD-TBR-06 limits the maximum opening size created by clearcutting, seed tree cutting, shelterwood seed cutting, or other cuts designed to regenerate an even-aged stand of timber in a single harvest operation to 40 acres. To trend towards the Forestlands desired conditions an exception to the 40-acre maximum opening size standard could occur when determined necessary to help achieve desired ecological conditions for the plan areas. The desired conditions include providing for forest patterns, patch sizes and forest resilience both in the short- and long-term. The maximum opening size exception for the Nez Perce-Clearwater is 207 acres.

This is an increase in the maximum opening size compared to the No Action Alternative that limits the maximum opening size to 40 acres. Although this does not mean that all proposed regeneration harvest units would reach 207 acres in size, there is a higher potential to affect water quantity when openings are larger. The maximum opening size represents the average patch size under natural range of variation conditions. See Appendix B for more information on maximum opening size. Desired conditions for early successional forest patches, or “openings”

With the proposed increase in maximum opening size for regeneration and other even-aged harvest and the proposed increase in timber harvest under all action alternatives, there is an elevated likelihood of increased cleared forest vegetation area persisting on the landscape at any given time in a given HUC12 or smaller catchment. By extension, there is also an elevated potential for observed changes in average annual water yield and peak flows. These openings, depending on the distribution and size of openings and the level of tree retention, could be within the natural range of variation. The effects of vegetative manipulation on water yield are complex, highly variable, and depend on many independent factors, such as elevation, climate, aspect, and especially precipitation. Appendix 4 of the Land Management Plan offers a possible management approach that could be used to assess changes to hydrologic flow regimes and help determine potential effects to water yield and peak flows associated with proposed project activities.

Consumptive surface water and groundwater uses would continue under all the action alternatives in alignment with existing water rights and regulatory authorities. Municipal Supply Watersheds and Source Water Protection Areas would continue to provide source water for their constituent communities (FW-DC-MWTR-01, FW-STD-MWTR-01).

Riparian Areas, Wetlands, and Floodplains

The 2012 Planning Rule requires Land Management Plans to include plan components to maintain or restore the ecological integrity of riparian areas in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity (36 CFR 219.8(a)(3)(i)). The 2012 Planning Rule also requires the establishment of widths for riparian management zones around all lakes, perennial and intermittent streams, and open water wetlands, giving special attention to land and vegetation for approximately 100 feet from the edges of all perennial streams and lakes (36 CFR 219.8(a)(3)(ii)).

The Riparian areas, wetlands, and floodplain function indicator addresses the potential for alteration of these geomorphic features and sensitive ecosystems. It is measured qualitatively by potential changes in riparian and wetland conditions and floodplain function.

System roads have the most notable impact to riparian and wetland conditions and floodplain function on the Nez Perce-Clearwater. There are approximately 1,600 miles of Forest Service system roads located within riparian management zones. More importantly, there are approximately 686 miles of Forest Service system roads located within 100 feet of stream channels, which equates to approximately seven percent of the total road system. Table 117 displays road miles and road surface material for open and closed system roads within 100 feet of stream channels. Some of these road miles are continuous along substantial lengths of a stream channel or are unconnected sections of road that interact with streams only at stream crossings. There are approximately 4,200 stream crossings associated with these roads. Risk of sediment delivery to streams is generally highest with native surface roads in close proximity to the stream channel and lowest with asphalt. Closed system roads, if stable, hydrologically disconnected, and revegetating, contributes less chronic sediment delivery than open roads.

Table 117. Road miles by surface material for open and closed system roads within 100 feet of stream channels

Road surface material	Miles of roads open to motorized traffic	Miles of roads closed to motorized traffic
Asphalt	51	0
Crushed aggregate or gravel	238	37
Bituminous surface treatment	1	0
Native material	196	163

Data Source: Nez Perce-Clearwater Geographic Information System.

In some areas, roads have interrupted the hydrologic connectivity of headwater streams to lower reaches, disrupting sediment and wood material transport downstream. Stream adjacent roads can also interrupt the connectivity of streams to floodplains and alter channel morphology. The effects increase with increases in the hydrologic connection of roads to the stream channel network (Jones and Grant 1996, Wemple et al. 1996). Roads that are closer to stream channels have a greater potential for sediment delivery to streams (Wemple et al. 1996). Sediment delivery to streams occurs primarily at road-stream crossings and secondarily by road-induced gullies (MacDonald and Coe 2008, Croke et al. 2005). Roads that bisect meadows and other wetland areas intercept and concentrate water through culverts, lowering the water table. As long as the road prism persists on the landscape, there is little to no chance for recovery of floodplain function or condition. Routine maintenance, hydrologically disconnecting roads, stormproofing roads, and site-specific improvements, however, can be made to mitigate impacts.

Numerous plan components are proposed to limit new impacts and reduce existing impacts from roads to riparian areas, wetlands, and floodplains by reducing hydrologic connectivity and sediment delivery (FW-DC-CWN-03, FW-STD-ARINF-07, FW-DC-ARINF-01, FW-GDL-ARINF-01, FW-GDL-ARINF-02, FW-GDL-ARINF-10); limiting road construction in riparian management zones (FW-GDL-RMZ-02), limiting sidecasting during road construction or reconstruction and maintenance (FW-STD-ARINF-03, FW-GDL-ARINF-07); and increasing the size of new, replacement, and reconstructed stream crossings to accommodate at least the 100-year flow (FW-STD-ARINF-04).

In areas with stream-adjacent roads there is higher hydrologic connectivity and sediment delivery to streams may not be able to be fully mitigated. Hydrologic connectivity cannot reach zero, as there will always be some remaining road segment that cannot be fully disconnected at stream crossings. However, implementation of best management practices can be employed to reduce the fraction of road surface erosion being delivered to streams at these locations (Sugden 2018).Stream crossing and road drainage failures on National Forest System lands initiated by intense precipitation or rain-on-snow events have caused extensive resource damage. Modification of stream crossings and control of road drainage, whether generated on the road surface or intercepted by the road cut and ditch, are the most important issues for preventing storm damage. Addressing streamside road locations, slope stability issues, and adequate vegetation erosion control are also important to reduce the risk of storm damage (Keller and Ketcheson 2015). Objective FW-OBJ-CWN-02 proposes stormproofing 10 to 20 percent of roads in Conservation Watershed Network areas prioritized for restoration every 5 years, as funding allows, to benefit threatened and endangered aquatic species. Stormproofing refers to nonrecurring treatments on existing roads that reduce the potential for resource impacts and damage or failure of a road feature or road system, typically resulting from storm events. These treatments relate to open and stored roads and include timely road maintenance; utilizing many key road drainage measures; reducing culvert diversion potential; pulling back marginal fill slopes; using biotechnical and vegetative slope stabilization and erosion control, gully prevention, bridge maintenance; and many other measures.

Public and general administrative road use is expected to remain consistent across the No Action Alternative and Action Alternatives. Due to proposed increases in the amount of vegetation management proposed for the Action Alternatives, road use related to timber harvest and associated log haul is expected to increase. For Alternative Z, log-haul traffic would be similar to the existing levels found under the No Action Alternative. Alternatives W, X, and Y and the Preferred Alternative have a higher risk of impact due to the amount of log truck traffic associated with proposed timber harvest.

As discussed in the Infrastructure section of the Final Environmental Impact Statement, increased log truck traffic can increase the amount of road sediment available for delivery to streams. There is a direct correlation between the volume of commercial timber sale traffic generated from Forest Service management activities and the volume of timber sold. Logging trucks hold roughly 5,000 board feet per truck, for a total weight of 80,000 pounds. The number of logging trucks and other commercial traffic on the roadways would be proportionate to increases or descreases of timber volume sold. For example, for the Preferred Alternative, timber outputs would be about 190 to 210 million board feet annually, which corresponds to roughly 38,000 to 42,000 commercial vehicles traveling Nez Perce-Clearwater roads annually. Increased log-haul multiplies the amount of aggregate breakdown. When this occurs near streams, the potential for sediment delivery is higher. The wear rate calculated in 2018 was estimated to be one inch per ten million board feet, varying by geologic parent material of the gravel, with basaltic and limestone gravels being more resilient than granitic gravels.

Because of the increase in log-haul traffic proposed in the Action Alternatives, there is a higher potential risk of sediment delivery to streams, especially from roads that are hydrologically connected or adjacent to streams. The associated road maintenance and road reconstruction can also be a source of sediment; pulses of road sediment created by road grading can elevate sediment delivery in the short-term, although improving stream sedimentation in the long run. On the other hand, higher timber volumes can also result in in a higher rate of positive road modifications, such as installing road drainage features at regular intervals, adding gravel surfacing on highly erodible soils, and replacement of failing or undersized culverts. Under timber stewardship sales, watershed improvements can be accomplished, including installation of aquatic organism passage culverts; bridge improvements; additional gravel surfacing; and replacement of additional drainage structures with upsized culverts, retaining walls, landslide repairs, and forestwide road maintenance, such as road blading.

Roads are considered necessary for social and economic sustainability. Not only are roads needed for managing the Nez Perce-Clearwater they also provide recreational opportunities and access important to local communities. To trend towards achievement of desired condition FW-DC-ES-01, ecosystem services guideline FW-GDL-ES-01 specifies that to provide for social and economic sustainability of rural communities, access to activities such as recreation, hunting, fishing, gathering, egress and wildfire management should continue to be provided for on routes or in areas designated as open to motorized use in the summer and winter. If a route is identified as substantially impairing aquatic ecological values, rerouting and route improvement should be considered prior to closure, to preserve motorized access opportunities. If a route or area needs to be closed, alternate motorized access to maintain social and economic sustainability of rural communities should be provided.

Although road decommissioning and storage could still occur if roads were causing natural resource impacts, the primary road treatment focus would be minimizing the impacts of roads to water and aquatic resources by hydrologically disconnecting roads from streams (FW-GDL-ARINF-01, FW-STD-ARINF-07), storm proofing roads (FW-OBJ-CWN-02), improving road conditions (FW-OBJ-INF-01, FW-OBJ-INF-02), and relocating roads out of riparian areas, wetlands, and floodplains (FW-WTR-OBJ-02, FW-WTR-OBJ-04, FW-OBJ-RMZ-01). Additionally, standard FW-STD-WTR-02 requires project-specific best management practices (BMPs), including both federal and state BMPs, to be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet water quality desired conditions, and to protect beneficial uses. The following are examples of potential road related best management approaches that could be incorporated into project implementation.

- Installing road drainage features at regular intervals to reduce erosion and divert overland flow from roads onto undisturbed hillslopes to promote water infiltration.
- Ensuring road runoff is disconnected from streams toward filtration areas.
- Revegetating and establishing ground cover on disturbed areas near streams (cutslopes, fillslopes, and road ditches).
- Adding gravel surfacing on highly erodible soils or when wet weather use is required.
- install supplemental filtration for suspended sediments where needed to prevent direct sediment delivery to streams, such as slash windrows, silt fences, straw bales, etc.
- Installing appropriately sized stream crossing structures that allow passage of flood flows, sediment, wood, and minimize disruptions to aquatic species movement.

- Managing or restricting seasonal road access to vehicles as needed to prevent rutting, and perform any necessary maintenance; such as road grading, culvert cleaning, or ditch cleaning; through time.

Riparian and wetland conditions and floodplain functions are expected to improve as the Nez Perce-Clearwater trends towards the Aquatic Ecosystems desired conditions and limits the amount of hydrologic connectivity, sediment delivery, and alteration of riparian areas that occur from roads. Relocation of streamside roads or roads in meadows could further improve riparian, wetland, and floodplain functions. Best management practices would be implemented with all management activities having the potential to affect water quality. Riparian Management Zones are not suitable for timber production as it would not be compatible with the achievement of desired conditions and objectives established by the plan for those lands (36 CFR 219.10 (a)(iii)). Timber harvest for purposes other than timber production could occur in riparian management zones. Timber harvest could be used as a tool to assist in achieving or maintaining one or more applicable desired conditions or objectives. Examples of using timber harvest to protect other multiple use values may include improving wildlife or fish habitat, thinning to reduce fire risk, or restoring meadow or savanna ecosystems where trees have invaded. Additionally, the use of prescribed fire, particularly under burning, may be desirable in riparian management zones to restore natural ecosystem function, reduce forest density or fuel loadings.

Riparian management zones are not intended as exclusion areas or reserves. Instead, management activities designed to benefit aquatic and riparian-dependent resources and move the landscape towards desired conditions are allowed and encouraged within them. Plan component FW-STD-RMZ-07 establishes default riparian management zone widths that can contain both upland and riparian vegetation. Although the default riparian management areas widths are uniform, the management of them is not intended to be.

Vegetation management in riparian management zones would be guided by the desired conditions for riparian and wetland vegetation (FW-DC-TE-05 FW-DC-GS-04) and riparian management zones (FW-DC-RMZ-01, FW-DC-RMZ-02). Proposed standards and guidelines were developed to reduce the risk of potential effects to riparian conditions, including the requirement of specific conditions before vegetation management and prescribed fire could occur within riparian management zones (FW-STD-RMZ-01, FW-STD-RMZ-06) and direction to avoid riparian management zones when constructing new permanent roads, temporary roads, landings, skidding trails, staging or decking areas, and machine burn piles (FW-GDL-RMZ-01, FW-GDL-RMZ-02). Vegetation management or prescribed fire could be used to achieve restoration of hardwoods (FW-OBJ-TE-01) and reduce conifer encroachment in meadows (FW-OBJ-GS-01).

The following standards have specific requirements for vegetation treatments in riparian management zones to help achieve or maintain the desired conditions or to avoid or mitigate undesirable effects, including harvest and fuels treatments in riparian management zones (FW-STD-RMZ-01), hazard tree management in riparian management zones (FW-STD-RMZ-05), and prescribed fire management in riparian management zones (FW-STD-RMZ-06). Site specific, interdisciplinary analysis at multiple scales would occur before actions proceed within riparian management zones. Restoration of riparian areas may be accomplished through passive management or may require active management, particularly in areas where natural disturbances, such as fire or flooding, have been prevented from occurring or if past projects and activities have altered riparian functions, such as where roads are located within riparian areas. Floodplain restoration can focus on enlarging the functional floodplain, reconnecting the channel and floodplain, restoring natural regimes of water, sediment, and/or large wood, or enhancing the spatial heterogeneity of the channel and floodplain. Each of these forms of floodplain restoration can increase floodplain storage and resiliency to natural and human-caused disturbances. The establishment of riparian management zones does not prohibit projects that may have short-term adverse effects to water conditions and fish habitat, if the actions maintain or restore structure, function, composition, and connectivity of riparian areas over the long term.

Restoration is emphasized in the Land Management Plan through objectives. Objectives related to improvement of riparian areas focus on improving riparian habitat, floodplain function, and hydrologic connectivity. Objectives specific to riparian areas include improving 300 to 700 acres of riparian habitat every 5 years (FW-OBJ-RMZ-01); restoring hardwood species or allowing disturbance processes, such as fire or other disturbance, on 3,000 to 4,200 acres of riparian areas every 5 years (FW-OBJ-TE-01); maintaining existing meadows and grasslands by reducing conifer encroachment into meadows and grasslands on 2500 acres every 5 years (FW-OBJ-GS-01); and increasing camas production on 50 acres of camas habitat every 5 years, primarily through wildland fire (FW-OBJ-TT-02).

The largest threats to springs, seeps, and groundwater dependent ecosystems are those that change water flow, temperature, or water quality of springs. Plan components that directly address springs include FW-DC-WTR-08, FW-GDL-WTR-05, FW-DC-TT-04 and FW-GDL-ARGRZ-03. These plan components provide guidance to maintain quality and quantity of water flows, and persist in size and seasonal and annual timing, exhibit water table elevations within the natural range of variability and sustain the function of surface and subsurface aquatic ecosystems. Diversions for livestock water developments and livestock use of springs can impact springs, seeps, and other groundwater dependent ecosystems. Add plan component for water developments. See Livestock grazing management section below under Effects to water resources from management of other resources.

For further information on riparian areas, see sections Forestlands, At-Risk Plant Species, Aquatic Ecosystems and Fisheries, and Abundance and Diversity of Wildlife in the Final Environmental Impact Statement.

Municipal Water Supplies and Source Water Protection Areas

The 2012 Planning Rule (36 CFR 219.8(a)(2)(iv)) requires that a plan include plan components to maintain or restore water resources in the plan area, including ground water; public water supplies; source water protection areas; and other sources of drinking water, including guidance to prevent or mitigate detrimental changes in water quantity, quality, and availability. It also requires that a plan include plan components for integrated resource management to provide for ecosystem services and multiple use [including watershed] (36 CFR 219.10(a)), considering riparian areas and surface and subsurface water quality (§219.10(a)(1)) and public water supplies and associated water quality (§219.10(a)(9)).

Water draining off the Nez Perce-Clearwater is often used for drinking water supplies. Municipal watersheds and source water protection areas are two separate constructs for drinking water protection that are applicable to National Forest System land management.

Municipalities may apply to the Forest Service for municipal watershed agreements if they desire protective actions or restrictive measures not specified in the Land Management Plan. Formal written agreements to ensure protection of water supplies may be appropriate when multiple use management fails to meet the needs of a water user. Although there are currently no municipal watershed agreements established for watersheds on the Nez Perce-Clearwater, agreements could be developed in the future.

Source water protection areas, as delineated by the Idaho Department of Environmental Quality, protect public water systems from contamination in accordance with the 1996 amendments to the Safe Drinking Water Act. Approximately 73,490 acres of the Nez Perce-Clearwater are delineated as source water protection areas for surface water intakes and 6,440 acres are delineated as source water protection areas for groundwater intakes.

The desire condition for municipal water supplies and source water protection areas is that lands that contribute to municipal watersheds and source water protection areas are in a condition that contributes to consistent delivery of clean water and meets or exceeds State of Idaho water quality standards (FW-DC-MWTR-01). To help trend towards this desired condition, standard FW-STD-MWTR-01. Requires management activities conducted in source water protection areas to be consistent with source water protections and goals. Short-term effects from activities in source water protection areas may be acceptable when those activities support long-term benefits to water quality. Best management practices would be implemented with all management activities having the potential to affect water quality (FW-STD-WTR-02).

A dilemma when managing municipal water supplies and source water protection areas is whether the watersheds should be placed under active or passive management regimes to sustain supplies of high-quality water over the long run. Some people think that water supplies can be best protected by actively managing these watersheds to maintain forest vegetation at a condition with low fire risk. Conversely, others believe that, in the interest of water quality, people should not alter watersheds in any way, other than to divert the water (Sedell et al. 2000).

Municipal watersheds are not considered suitable for timber production, although timber harvest is suitable to meet other resource desired conditions. Under the Action Alternatives the treatment of forested vegetation in watersheds containing municipal water supplies and source water protection areas would trend towards the Forestlands desired conditions.

Consumptive surface water and groundwater uses would continue under all the Action Alternatives in alignment with existing water rights and regulatory authorities.

Effects that Vary by Action Alternative

Although desired conditions, standards, and guidelines are the same for Action Alternatives, land allocation and suitability, including recommended wilderness and recreation opportunity spectrum do differ between Action Alternatives. Although actions likely to be taken and activities likely to occur under these alternatives may differ, the effects of are not expected to be different to watersheds and water resources due to the universal application of aquatic ecosystem plan components under all Action Alternatives.

The primary difference between Action Alternatives is the pace and scale at which the treatment of forest vegetation trends toward Forestlands and Fire Management desired conditions. The amount of proposed vegetation treatment varies by Action Alternative and directly correlates to the rate of achieving vegetation desired conditions, as described in the Forestlands section. Proposed vegetation treatments range from 3,700 to 14,000 acres per year for the Action Alternatives, compared to 4,300 annual acres in the No Action Alternative. The Preferred Alternative proposes 8,825 to 10,000 acres per year. As discussed in the riparian, wetland, and floodplain function under the effects common to all alternatives. The amount of log haul associated with timber harvest has the potential to affect water resources. Due to the programmatic nature of the draft EIS, it is difficult to determine the effects of alternatives with respect to the use of roads during timber harvest. The effect of log haul traffic on aquatic resources is dependent upon a number of variables, such as, but not limited to: road surface, miles to access harvest units, number of stream crossings, proximity of a road to a stream, and amount of timber removed. These types of impacts are evaluated on a project-specific basis.

The numerous standards and guidelines that are proposed to limit the amount of sediment delivery or alteration of hydrologic flow regime from roads would help to mitigate undesirable effects. They include limits on sidecasting of road material or snow (FW-STD-ARINF-03, FW-GDL-ARINF-07); routing road drainage away from streams and unstable slopes (FW-GDL-ARINF-09, FW-GDL-ARINF-02); requiring upgrading or removal of stream crossings (FW-STD-ARINF-04, FW-GDL-ARINF-03, FW-GDL-ARINF-05, FW-GDL-ARINF-11); avoiding high mass wasting potential areas and wetland areas (FW-GDL-ARINF-04, FW-GDL-ARINF-08); and requirement of incorporating best management practices into project planning (FW-STD-WTR-02). Standard FW-STD-ARINF-07 requires that when constructing or reconstructing roads in the Conservation Watershed Network and HUC12 subwatersheds with Endangered Species Act critical habitat or listed aquatic species, projects shall result in a net decrease in the hydrologic connectivity of the road system and stream channel network.

Table 118 displays the water and aquatic resources restoration objectives that vary by alternative. Alternatives W and X would result in the highest volume of timber production and, therefore, would have the potential to generate increased revenue from timber receipts that could be available for watershed and aquatic restoration projects. Proposed miles or acres are proportional to the level of proposed timber harvest for each alternative. For example, road reconstruction and road improvement would primarily be accomplished during implementation of integrated projects that include timber harvest. Watershed restoration projects are intended to occur as integrated treatments strategically located and implemented at the watershed scale, primarily in priority and conservation watershed network watersheds.

Table 118. Water and aquatic resources restoration objectives by alternative

Restoration action	No Action (2013 to 2022)	Alt W	Alt X	Alt Y	Alt Z	Preferred
FW-OBJ-WTR-01. Number of priority watersheds where actions identified in watershed restoration action plans are completed every 15 years.	3	18	20	15	10	15
FW-OBJ-WTR-05. Acres of improved soil and watershed conditions every 5 years with emphasis on priority and conservation watershed network watersheds. This includes non-system road decommissioning.	1,520	5,000	5,300	4,000	2,500	3,000-4,000
FW-OBJ-CWN-02. Percent of roads in Conservation Watershed Network watersheds storm proofed every 5 years. There are approximately 3,900 miles of road within CWNs. Under the preferred alternative 15% every 5 years would equate to approximately treating 585 miles every five years.	NA	20	20	15	10	15

Restoration action	No Action (2013 to 2022)	Alt W	Alt X	Alt Y	Alt Z	Preferred
FW-OBJ-INF-01. Miles of road reconstructed or roads improved every 5 years with focus on roads with chronic sediment delivery to streams or potential future road prism failures.	500	1,000	1,100	600	300	600
FW-OBJ-INF-02. Miles of operational Maintenance Level 2 through 5 roads maintained annually.	1,100	1,900	2,000	1,400	1,000	1,400

Cumulative Effects

Stream systems on the Nez Perce-Clearwater originate in high elevation headwater drainages and flow downstream through the Nez Perce-Clearwater onto lands owned or administered by entities other than the Forest Service. The streams ultimately flow into the Clearwater, Salmon, Snake, and Spokane rivers. Water is an ecosystem service provided by the Nez Perce-Clearwater that is important in the broader landscape outside the plan area and is likely to be influenced by the Land Management Plan. Water that originates on the Nez Perce-Clearwater provides many important benefits, including public drinking water, recreational opportunities, aesthetics, fishing opportunities, water for fish and wildlife, livestock watering, and irrigation. Additionally, water quality and supply are important for ecological sustainability, which contributes to the many benefits and ecosystem services that people derive from the Nez Perce-Clearwater.

Portions of the Nez Perce-Clearwater adjoin five other national forests, each having its own Land Management Plan. The Nez Perce-Clearwater is also intermixed with lands of other ownerships, including other federal, state, and private lands. Some of these entities develop and implement their own resource management plans. Management plans from other federal and state agencies and the Nez Perce Tribe are summarized in Table 119. Actions, strategies, and prioritization of activities under these management plans, in conjunction with the Nez Perce-Clearwater Land Management Plan, cumulatively affect water resources at the landscape scale.

Table 119. Summary of cumulative effects to water resources from other resource management plans

Resource Plan	Description and Summary of Effects
Adjacent National Forest Land Management Plans (U.S. Department of Agriculture 2010d, 2018h, 1987d, 1986a, 2015c)	Land management plans for National Forest System lands adjacent to the Nez Perce-Clearwater include the Payette, Wallowa-Whitman, Bitterroot, Lolo, and Idaho Panhandle National Forests. All plans address water resources management and watershed management would be complementary. Water resources management is fairly consistent across all national forests due to law, regulation, and policy, and plan components are relatively consistent and compatible with overall direction.
Bureau of Land Management Cottonwood Resource Management Plan (U.S. Department of the Interior 2009)	Bureau of Land Management lands near the Nez Perce-Clearwater are managed by the Cottonwood field office. The Cottonwood Resource Management Plan contains components similar to the Pacific Anadromous Fish Strategy and would be complementary to the plan components proposed in the revised Land Management Plan.

Resource Plan	Description and Summary of Effects
Nez Perce Tribe Integrated Resource Management Plan (Tribe 2023)	The protection and enhancement of water quality and restoration of degraded hydrologic systems are high priorities. This Plan includes desired conditions for water resources that would be complementary to the plan components proposed in the revised Land Management Plan.
The Idaho Forest Action Plan Resource Assessment and Resource Strategy (Idaho Department of Lands 2020)	Identified water quality and quantity as benefits, which depend on maintaining ecological integrity and sustainable use of forests. This plan is complementary to the revised Land Management Plan related to the protection and management of water resources. The Idaho Shared Stewardship Initiative will focus on treating prioritized landscapes by promoting cross-boundary work on state, private, tribal, and Federal lands to protect communities from wildfire, improve forest and watershed health, and sustain jobs and local economies in Idaho.
State of Idaho, Source Water Protect Plans (see Appendix K)	The communities of Kamiah, Orofino, Lewiston, Juliaetta, Pierce, and Riverside derive their domestic water supply directly from the surface water originating from within the Nez Perce-Clearwater. The communities of Grangeville, Kooskia, and Potlatch derive groundwater that drains from Nez Perce-Clearwater lands. The proposed Land Management Plan would be consistent with community specific source water protection plans.
Idaho Ground Water Quality Plan (Ground Water Quality Council 1996)	This Plan protects ground water quality for public use and provides guidance to state agencies, local governments, and citizens to prevent ground water contamination. The Plan establishes the basis for protecting ground water now and for future generations and preventing contamination whenever possible. The plan also helps agencies develop management programs and regulations and implement ground water quality protection strategies. It is intended to work in conjunction with the Idaho State Water Plan. The proposed Land Management Plan would be consistent with the Idaho Ground Water Quality Plan.
Idaho State Water Quality Management Plan (https://www.deq.idaho.gov/water-quality/planning-and-administration/)	The Plan is not a single plan or document but rather a compilation of the guidance and programs Idaho Department of Environmental Quality uses to implement Clean Water Act requirements. It describes how the state's water resources are managed and describes how Idaho manages water quality. The Plan follows a continuing planning process and outlines laws, rules, and guidance; water quality programs; monitoring and assessment; implementation; planning; and public involvement. The proposed Land Management Plan would be consistent with the Idaho State Water Quality Management Plan.
Idaho Comprehensive State Water Plan (Idaho Department of Water Resources 2012)	The plan includes the statewide water policy plan and associated component basin and water body plans, which cover specific geographic areas of the state. The Plan guides the development, management, and use of the state's water and related resources. The proposed Land Management Plan would be consistent with the Idaho Comprehensive State Water Plan.

Landscape or watershed scale restoration requires an interdisciplinary effort and necessitates close coordination between multiple resource programs, watershed councils, adjacent landowners, stakeholders, partners, and interested parties. Cooperation can result in large benefits and returns on investments because mutual priorities and opportunities are identified and resources can be pooled to accomplish conservation and restoration actions. The Land Management Plan stresses the importance of coordination by including goal FW-GL-WTR-02, which emphasizes that the Nez Perce-Clearwater builds and maintains partnerships to fund and implement projects that result in improved water quality and watershed and stream conditions.

Effects to Water Resources from Other Resources

Effects listed in this section are shared across all action alternatives, unless otherwise noted. Management from the following resources or designations do not affect water resources or the ability to manage water resources: carbon storage and climate change, wildlife, air quality, scenery, Idaho roadless areas, research natural areas, geographic areas, and special areas.

Terrestrial Ecosystems Across the Landscape

Plan components in the Terrestrial Ecosystems Across the Landscape section of the Land Management Plan provide management direction that supports the maintenance or improvement of watersheds, riparian areas and wetlands and is the same for all Action Alternatives. There is a desired condition for peatlands, including fens and bogs, to have the necessary soil, hydrologic, water chemistry, and vegetative conditions to provide for continued development and resilience to changes in climate and other stressors (FW-DC-TE-02) Additional desired conditions promote vegetation that reflects natural disturbance regimes (FW-DC-TE-04 and riparian vegetation includes native assemblages of hardwood trees, deciduous shrubs, conifers, and, where appropriate, unique coastal disjunct species (FW-DC-TE-05). To trend towards these desired conditions the Land Management Plan includes an objective to restore hardwood overstory and understory species or allow disturbance processes, such as fire or other disturbance, on 3,000 to 4,200 acres of riparian areas every 5 years (FW-OBJ-TE-01).

The beneficial effects to water resources from terrestrial ecosystems management would be the same under all Action Alternatives.

Cave and Karst Features

Caves include any naturally occurring void, cavity, recess, or system of interconnected passages beneath the surface of the Earth or within a cliff or ledge. Karst features are geological landforms that predominantly result from the shaping process controlled by soluble bedrock. Karst features create unique microhabitats and are important areas for rapid subsurface drainage and aquifer recharge. The desired conditions for cave and karst features for all the Action Alternatives are that hydrological resources are protected and maintained (FW-DC-CAVE-01) and that water flowing into, from, or within caves is not altered or diverted in its flow; contains normally fluctuating background levels of sediment, organic matter, and dissolved minerals; and is not polluted (FW-DC-CAVE-03). The beneficial effects from cave and karst management would be the same under all Action Alternatives.

Forestlands Management and Timber Harvest

The plan components in the Forestlands section were developed to increase forest resilience and to maintain or restore the composition, structure, function, and connectivity of terrestrial ecosystems, considering multiple spatial and temporal scales. The exact location of future timber harvest would depend largely on factors of road access and site-specific forest conditions relative to the desired conditions as outlined in the Land Management Plan. However, uncertain disturbance events would also influence location and extent of harvest.

Watershed conditions and water resources could potentially be impacted by the Forestland desired conditions and objectives and the timber objectives under all Action Alternatives. Although, the proposed amount of vegetation management varies by Action Alternative, there is little differentiation of impacts to water resources between the alternatives when viewed at the Forest scale.

Broadly, the desired conditions for terrestrial vegetation on the Nez Perce-Clearwater are characterized by improvements in species composition, desirable densities, and general forest health and condition; vigorous non-forested plant communities; and maintaining native biodiversity on the landscape. The desired conditions are consistent with the Forest Service's understanding of the natural range of variation and are most likely to be resilient in the future given expected drivers, such as climate change, drought, vegetation succession, wildfire, insects and disease, and the demands of people. Overall, the restoration of forested ecosystems and trend towards reestablishing historical fire regimes would benefit watersheds and water resources in the long-term by restoring ecological integrity and resiliency of forested ecosystems.

The amount of proposed vegetation restoration varies by alternative and directly correlates to the rate of achieving vegetation desired conditions, as described in the Forestlands section. Proposed vegetation restoration ranges from 3,700 to 14,000 acres per year for the Action Alternatives, compared to 4,300 annual acres in the No Action Alternative. The Preferred Alternative proposes 8,825 to 10,000 acres per year. Although, the proposed amount varies by Action Alternative, there is little differentiation between the alternatives when viewed in the larger context. The proposed acres equate to 0.3 to 1.1 percent of Management Area 3 and 0.1 to 0.3 percent of the Nez Perce-Clearwater per year. The potential risk to water resources from vegetation restoration is not so much the amount of area harvested but how those acres are concentrated or distributed across the landscape and if units are located in or near areas with high resource concerns. The exact locations of timber harvest openings and how they are arranged across a watershed cannot be determined during programmatic analysis.

With the proposed increase in timber harvest under all action alternatives, there is an elevated likelihood of increased cleared forest vegetation area occurring on the landscape at any given time in a specified Hydrologic Unit Code (HUC) 12 or smaller catchment. By extension, there is also elevated potential for observed changes in average annual water yield and peak flows. These openings could be within the natural range of variation depending on distribution and size of openings and the level of tree retention.

Changes in the amount or distribution of vegetation can affect water quantity and ultimately alter stream channel conditions. The Forestlands desired conditions emphasize landscape and within-patch patterns that reflect historic fire regimes, which would include increasing amounts and size of early seral openings. The desired condition (FW-DC-WTR-07) for hydrologic flow regimes is that instream flows are sufficient to create and sustain riparian, aquatic, and wetland habitats and to retain patterns of sediment, nutrient, and wood routing. The timing, magnitude, duration, and spatial distribution of peak, high, and low flows are retained. Stream flow regimes maintain riparian ecosystems and natural channel and floodplain dimensions. Stream channels transport sediment and woody material over time while maintaining reference dimensions (for example, bankfull width, depth, entrenchment ratio, slope, and sinuosity).

The effects of vegetative manipulation on water yield are complex, highly variable, and depend on many independent factors such as elevation, climate, aspect, and especially precipitation. The management approach for plan component FW-DC-WTR-07 in Appendix 4 provides methodologies to assess the potential effects on water yield and peak flows associated with proposed project activities.

Timber harvest and associated temporary roads, skid trails, landings, and site preparation can create ground disturbance, which can result in erosion and sediment delivery to streams. Soil compaction can also alter infiltration rates, potentially to increasing overland and channelized flow. The desired condition for sediment regimes is that sediment delivery to streams is of the types, quantities, and rates that support the natural instream sediment transport and storage rates and instream sediment substrate composition. The sediment regime in water bodies is not chronically affected by management activities to the extent that the availability of functioning spawning areas and interstitial spaces are reduced (FW-DC-WTR-06).

Sediment was a primary cause for streams on the Nez Perce-Clearwater to not meet beneficial uses and be listed as impaired by the Idaho Department of Environmental Quality. It is desired that water quality, including groundwater, meets or exceeds applicable state water quality standards, fully supports designated beneficial uses, and is of sufficient quality to support surrounding communities, municipal water supplies, and natural resources (FW-DC-WTR-05). To help trend towards that desired condition, Standard FW-STD-WTR-06 requires management activities in watersheds with approved total maximum daily loads to be designed to comply with the total maximum daily load allocations following project implementation. Additionally, best management practices, including both federal and state, shall be incorporated in land use and project plans as a principal mechanism for controlling non-point pollution sources to meet soil and watershed desired conditions and to protect beneficial uses (FW-STD-WTR-02).

The Nez Perce-Clearwater also proposes to limit the amount of sediment delivery to streams by hydrologically disconnecting roads, skid trails, temporary roads (FW-GDL-ARINF-01); avoiding construction of new road, temporary road, trail, and landings in riparian management zones (FW-GDL-RMZ-01); and limiting ground disturbing activities in riparian management zones from harvest activities (FW-GDL-RMZ-02, FW-GDL-RMZ-03). In addition, FW-STD-TBR-02 would provide further protections by requiring timber to not be harvested on lands where soil, slope, or other watershed conditions would be irreversibly damaged, as identified in project-specific findings.

Vegetation management can also benefit watershed condition. Vegetation departure, fire regime, and forest health are included in the watershed condition classification process as indicators that represent the underlying ecological functions and processes that affect soil and hydrologic function. Vegetation management, including wildland fire, can help achieve desired condition FW-DC-WTR-01. The desired condition is that National Forest System lands provide the distribution, diversity, and complexity of watershed and landscape-scale features, including natural disturbance regimes and the aquatic and riparian ecosystems to which species, populations, and communities are uniquely adapted. Watersheds and associated aquatic ecosystems retain their inherent resilience to respond and adjust to disturbances, including climate change, without long-term, adverse changes to their physical or biological integrity.

Riparian management zones are not exclusion zones but areas where vegetation management is allowed to occur when guided by the desired conditions for aquatic resources associated with riparian areas and wetlands (FW-DC-TE-05, FW-DC-GS-04) and riparian management zones (FW-DC-RMZ-01, FW-DC-RMZ-02). Proposed standards and guidelines were developed to reduce the risk of potential effects to water quality, including the requirement of specific conditions before vegetation management could occur within riparian management zones (FW-STD-RMZ-01) and direction to avoid riparian management zones when constructing new permanent roads, temporary roads, landings, skidding trails, staging or decking areas, and machine burn piles (FW-GDL-RMZ-01, FW-GDL-RMZ-02). Vegetation management could be used to achieve restoration of hardwoods (FW-OBJ-TE-01) and reduce conifer encroachment in meadows (FW-OBJ-GS-01).

See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to timber harvest and vegetation management for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

Fire Management

As described in the Forestlands and Fire Management sections of the Final Environmental Impact Statement, vegetation conditions are departed from the natural range of variation. The primary causing factor is fire exclusion due to active fire suppression over the last 100 years. The historic pattern of disturbance has also been altered, particularly in short fire return interval areas. Fuel accumulations, coupled with warmer, drier weather in the past decade, have resulted in the current trend of larger and higher intensity fires. This is a departure from the historic pattern where a variety of fire intensities occurred on the landscape.

Fire is a natural disturbance process that has historically influenced watershed conditions, including riparian and wetland areas. Fire is encouraged to function as a natural process across the Nez Perce-Clearwater, especially within designated wilderness and Idaho roadless areas. The aim of desired condition FW-DC-FIRE-01 is for landscapes across the Nez Perce-Clearwater to be resilient to fire-related disturbances in accordance with management objectives. Natural fuel conditions emulate the structure, species mix, spatial pattern, extent, and resiliency of the historic fire regime of the area. Wildland fires burn with a range of intensity, severity, and frequency that allows ecosystems to function in a healthy and sustainable manner and meet desired conditions for other resources.

Wildfire removes hillslope vegetation, which can decrease soil water storage and increase surface runoff and erosion. Wildfires can also affect water chemistry, water quantity, and stream channel structure through changes in transpiration, infiltration, ground water recharge, mass wasting, riparian shading, and the recruitment and delivery of coarse debris (Moody and Martin 2001a, Benda and Dunne 1997, Gresswell 1999, Moody and Martin 2001b, Wondzell 2001). However, these impacts are within the natural range of variation. Wildland fire provides more beneficial effects to watershed conditions than negative effects by promoting natural ecological processes.

Wildfire exclusion has allowed fuel loads to accumulate above natural levels in some areas of the Nez Perce-Clearwater. In these areas, when wildfire does occur, the intensity and severity may be higher than would occur under natural conditions. This process can change infiltration characteristics of soil and change hydrologic flow attributes. Severe fires may also remove virtually all vegetation and ground cover and result in soil erosion and sedimentation to nearby water bodies. Long-term fire exclusion allows forest successional processes to continue, which can increase evapotranspiration and interception, potentially resulting in less available water. In some areas, lack of fire can lead to the encroachment of woody species and trees into meadow habitats, which could lead to competitive exclusion of herbaceous species.

Prescribed Fire

The Nez Perce-Clearwater is characterized as fire-adapted or fire-dependent and requires periodic fire to maintain a healthy, resilient condition. Within these ecosystems, prescribed fire can help restore and sustain long-term environmental health. A prescribed fire is a planned fire intentionally ignited by fire specialists to meet management objectives. Prescribed fires are analyzed differently than the fire associated with site preparation after timber harvest and are used to reintroduce fire disturbance on the landscape and to meet a variety of vegetation, wildlife, and watershed desired conditions. Prescribed fires allow for a better controlled scenario when compared to a wildfire occurring under extreme climate conditions.

Effects to water resources would vary depending on the management objective. Underburning in drier potential vegetation types results in low and moderate burn severity that retains much of the soil groundcover and forest floor. A mixed burn severity prescription in more moist potential vegetation types could lead to the loss of ground cover in areas of moderate to high burn severity and potentially increase soil erosion, although recovery generally occurs in one to three years, depending on the amount and spatial distribution of remaining ground cover. Across blackened areas, the net effect of the burn residue and surface sealing of soil pores can exacerbate erosion potential by slowing infiltration (Larsen et al. 2009, Wondzell and King 2003). This post-burn condition is highly variable spatially and decreases over time (Doerr et al. 2006).

Prescribed fire would promote the re-establishment of fire-adapted ecological processes and help create desired forest compositions and structures. Use of fire as a tool within riparian management zones would likely occur to a similar extent under all action alternatives because of the potential ecological benefits and ability to help maintain or achieve desired vegetation conditions within riparian management zones. Proposed standard FW-STD-RMZ-06 specifies the requirements of prescribed fire used in riparian management zones. Prescribed fire could be used to achieve restoration of hardwoods (FW-OBJ-TE-01) and reduce conifer encroachment in meadows (FW-OBJ-GS-01).

Although there is a potential for temporary loss of ground cover and soil erosion, the effects are within the natural range of variation. The reintroduction of fire provides more beneficial effects to watershed processes and water resources than negative effects and promotes overall watershed resiliency. Although the proposed amount of prescribed fire varies by Action Alternative, there is little differentiation of impacts to water resources between the alternatives when viewed at the Forest scale.

Mechanical Fuels Treatments

Fuel characteristics strongly influence fire behavior and the resulting fire effects on ecosystems. Exclusion of fire causes fuel loads to accumulate above natural levels in some forest types. When wildfire occurs in these areas, the intensity and severity are often higher than they would be with more natural levels of fuel. Reducing hazardous fuels though mechanical treatments can reduce fire hazards, especially in wildland urban interface areas. The Nez Perce-Clearwater would continue to treat fuels using a combination of mechanical thinning or masticating; machine piling and burning; hand thinning, piling, and burning; hand thinning and chipping; and underburning.

Acknowledging that fuel treatments often require the use of ground-based mechanical equipment that have the potential to impact water resources, effects would be similar to those discussed in the vegetation and timber management section above and the same plan components would apply.

Fire Suppression Operations

Wildfire management consists of actions that are applied to wildfires based on a variety of factors, such as safety, economics, social considerations, and anticipated environmental effects. When a wildfire occurs, the first priority is the protection of human life and the safety of the public and firefighters. All alternatives would have similar direction for fire suppression operations, so the effects are common to all alternatives. Management strategies and methods vary depending on which management area a wildfire occurs. Wildfires occurring in Management Area 1 and Management Area 2 locations may be managed as resource benefit fires and little active suppression actions occur. In Management Area 3 locations, more active fire suppression methods are used.

As it is nearly impossible to predict the extent and location of future wildfires, quantifying the effects to water resources is difficult. Effects for suppression of wildfires occurring in Management Area 1 and Management Area 2 locations would be similar as described in the prescribed fire section above due to less occurrence of active fire suppression tactics. This would vary depending on fire severity. Fire suppression of wildfires occurring on Management Area 3 lands and wildland urban interface areas would likely have greater impacts as more ground disturbing methods are used. Fire suppression operations, such as construction of machine fire lines and establishment of large fuel breaks, can cause loss of ground cover, soil compaction, and rutting, all of which can affect water infiltration and increase overland or channelized flow. Depending on the extent of ground disturbance, soil erosion and subsequent sediment delivery to streams could occur. Fire suppression activities also have the potential to affect channel stability when water is drafted from streams to fill water storage tanks. Water is often ponded at a culvert inlet to deepen the “pool” so that water can be pumped out of the stream. Depending on how long the ponding occurs, it can alter channel structure long-term. To protect channel conditions, the following guideline is proposed – water drafting sites should be located and managed to minimize adverse effects on stream channel stability, sedimentation, and instream flows needed to maintain riparian resources, channel conditions, and fish habitat (FW-GDL-WTR-04).

In some instances, the creation of fuel breaks can cause equal or greater impact to water resources than timber harvest activities. In an effort to address public safety concerns in emergency situations, strict controls on acceptable activities, such as those implemented through timber harvest contracts or developed through rigorous project planning, may not be feasible, desired, or embraced by fire managers. Impacts resulting from past fire suppression activities have sometimes been observed to be long-lasting and extensive in scope.

The Action Alternatives would minimize these effects by limiting fire suppression activities away from riparian management zones (FW-GDL-WTR-07, FW-GDL-RMZ-06) and locating incident bases, camps, helibases, helispots, staging areas, and other centers for incident activities away from riparian areas where risk of sedimentation and risk of degradation to water quality are highest (FW-GDL-RMZ-05). Aerial application of chemical retardant, foam, or other fire chemicals and petroleum would be avoided in mapped aerial retardant avoidance areas to minimize impacts to the riparian management zones and aquatic resources (FW-GDL-RMZ-04). Additionally, guideline FW-GDL-INV-02 specifies that equipment, including pumps used to draft water from water bodies, water tenders, and helicopter buckets, should be inspected and cleaned for aquatic invasive species prior to use in a water body or when moving between subbasins (HUC08).

Additionally, all suppression activities would follow protocols outlined in the Guide to Preventing Aquatic Invasive Species Transport by Wildland Fire Operations (National Wildfire Coordinating Group 2017a), the Northern Rockies Coordinating Group Supplemental (Northern Rockies Coordination Group 2018b), and the Northern Rockies Coordinating Group Directive on Aquatic Invasive Species Protocols (Northern Rockies Coordination Group 2018b). Fire operations would follow industry standards for invasive species decontamination, such as vehicle washing. Rehabilitation efforts after fire suppression operations would help to mitigate many of impacts to water resources. Standard FW-STD-SOIL-02 requires impaired soil function created through management activities, including fire suppression, shall be rehabilitated to reestablish soil function to the appropriate site potential. In addition, guideline FW-GDL-RMZ-07 requires restoration of fire suppression activities in riparian management zones and guideline FW-GDL-INV-03 specifies that measures should be used to address invasive weed management when rehabilitating areas burned by wildfire and affected by wildfire suppression.

See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section regarding fire management for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives. The effects to water resources from wildfire suppression would be the same for all Action Alternatives.

Meadows, Grasslands, and Shrublands Management

Under the Action Alternatives, the Land Management Plan includes six desired conditions that promote meadows, grasslands, and shrublands resilience and support native plant communities (FW-DC-GS-01 to 06). Desired condition FW-DC-GS-04 specifically encourages wetland graminoid and riparian shrub habitat type groups that are comprised of a mosaic of communities dominated by native species which tolerate and are adapted to periodic flooding and an associated seasonally high-water table. These communities may be dominated by native graminoids, such as water sedge *(Carex aquatilis)* and tufted hairgrass *(Deschampsia cespitosa)*, and a variety of native forbs. Native shrubs include willow *(Salix spp.),* dogwood *(Cornus spp)*, and alder *(Alnus spp.). Native hardwood trees such as aspen (Populus tremuloides),* birch (*Betula occidentalis*), and cottonwood (*Populus spp.*) occur with other native mesic species in both riparian and upland communities. Invasive plant species either are not present or occur with low cover.

The Land Management Plan also includes an objective to maintain existing meadows and grasslands by reducing conifer encroachment into meadows and grasslands on a minimum of 500 acres every 5 years (FW-OBJ-GS-01). The beneficial effects from meadows, grasslands, and shrublands management would be the same under all Action Alternatives. Meadows are included as riparian management zones under the Action Alternatives and riparian habitat conservation areas under the No Action alternative and would be managed similarly.

Invasive Species and Invasive Species Management

Invasive species occur in most subwatersheds across the Forest. Invasive plants can compete and displace desirable native vegetation, alter effective ground cover, and disrupt natural ecological processes. Aquatic invasive species are non-native plants, animals, and microorganisms living in aquatic habitats that have the potential to impair aquatic ecosystem conditions. The Land Management Plan includes plan components to limit the extent of invasive plant species (FW-DC-INV-01) and aquatic invasive species (FW-DC-INV-02). Land Management Plan objective FW-OBJ-INV-01 proposes to treat 6,000 acres annually to contain or reduce non-native invasive plant density, infestation area, or occurrence.

Invasive plants are often treated using an integrated approach, with a combination of control types that include prevention, early detection, manual, biological, cultural, and chemical methods. Prevention may be constraints to activities, such as equipment decontamination and exclusion from infested areas. Manual treatments, essentially hand pulling, can result in localized soil disturbance as plants are removed. It is very labor intensive and costly; thus, only a small amount of acres per year could be treated using this technique. There are no effects to the soil resource from biological control methods, as there is no disturbance of ground cover or soil. Cultural methods generally involve enhancing the desirable vegetation to minimize invasive plant invasion. Planting or seeding desirable species to shade or out-compete invasive plants are common cultural treatments.

Effects from herbicide application depend on the type, extent, and amount of herbicide that is used, the proximity to a stream or wetland, the ratio of surface area to volume of a stream, and whether transport from the site is runoff or infiltration controlled. Chemical persistence in the soil profile depends on the soil texture, infiltration rate, chemical half-life, local climate, and the size of the treatment area. Effects of herbicide treatment to groundwater and surface water would be localized. Applications would occur at the appropriate time of year, considering targeted species and environmental factors. Adverse impacts to water resources are controlled through limits on herbicide type and application rates outlined in various NEPA documents. Where discharges of biological and chemical herbicides would leave residues in waters of the United States, a National Pollutant Discharge Elimination System permit would need to be obtained for those activities to comply with Section 301(a) of the Clean Water Act. Although most of the risk to water quality from chemical application may be reduced by applying best management practices, they cannot be eliminated. The proposed Land Management Plan includes specific directions for invasive weed treatment in and around riparian management zones to protect water quality (FW-STD-RMZ-03).

Soils Resource Management

All activities associated with management of the soils resource would benefit water resources. Soil impairment, such as loss of ground cover, soil compaction, and rutting, can affect water infiltration and increase overland or channelized flow. Depending on the extent of ground disturbance, soil erosion and subsequent sediment delivery to streams could occur. The proposed desired conditions, standards, and guidelines for the Soils Resources provide for protection of soils, limit soil impacts, and/or require soil rehabilitation. The beneficial effects from soils resource management would be the same under all Action Alternatives.

Aquatic Ecosystems Management

The beneficial effects from aquatic ecosystems management to watersheds and water resources would be the same under all Action Alternatives. Restoration actions associated with aquatic ecosystem objectives have to potential to create short-term impacts, but would provide for long-term benefit. The desired condition is that watershed restoration projects promote the long-term ecological integrity of aquatic ecosystems and conserve the genetic integrity of native species (FW-DC-WTR-12). Restoration projects would include best management practices during implementation.

Tribal Trust Responsibilities

The Tribal Trust Responsibilities section of the Land Management Plan provides management direction that either does not impact water resources or supports the maintenance or improvement of water resources and is the same for all Action Alternatives. Desired condition FW-DC-TT-04 promotes hot springs that are natural and free flowing in function and appearance. The hydrological, biological, and aesthetic resources in and around them are preserved, and are accessible for traditional cultural uses. Water quality meets state water quality standards for beneficial uses. Human use impacts are minor and consistent with traditional cultural uses of the site. The beneficial effects to water resources from managing tribal trust responsibilities would be the same under all Action Alternatives.

Cultural Resource Management

Historic properties are protected from project activities through the commonplace adherence to existing federal laws. Existing federal laws include the Antiquities Act of 1906 (16 U.S.C. 431), Historic Sites Act of 1935 (16 U.S.C. 461), National Historic Preservation Act of 1966 (NHPA) (16 U.S.C. 470), Archeological and Historic Preservation Act of 1974 (AHPA) (16 U.S.C. 469), Archaeological Resources Protection Act of 1979 (ARPA) (16 U.S.C. 47Oaa et seq.), and Native American Graves Protection and Repatriation Act of 1990 (NAGPRA) (25 U.S.C. 3001), and executive orders 11593, 13007, 13175, 13287 and 13327.

Activities, such as road decommissioning, road reconstruction, culvert replacement, meadow restoration, mine tailing removal, and riparian habitat restoration, can disturb or remove historic or prehistoric sites and have the potential to adversely affect non-renewable heritage resources. Managing for the protection of cultural resources has the potential to hinder implementation of watershed restoration activities. This constraint originates from federal law. There are no Land Management Plan components that restrict restoration activities. The effect to water resources from cultural resource management would be the same for all alternatives.

Sustainable Recreation Management

This section addresses non-motorized trails; motorized and non-motorized winter recreation; administrative sites; developed recreation sites, such as campgrounds; and dispersed sites.

Development sites and campground facilities in riparian areas can result in surface disturbance, leading to sediment increases to nearby streams; loss of stream bank vegetation; altered stream bank stability; and reduced water infiltration.

Associated human activities, such as off-highway vehicle use on trails and stream bank trampling, can also decrease ground cover and increase erosion. Recreational activities can cause soil compaction and loss of vegetation in wetlands and/or directly adjacent to them. This can also reduce subsurface water flow and increase surface runoff. Increases in surface runoff may contribute sediment to streams and associated aquatic habitats, depending on the proximity or connectivity to the hydrologic network.

Facilities can act similarly to roads in terms of potential effects by interrupting natural flow paths and rerouting of water. Additionally, administrative sites and developed recreation sites can impact water quality through spills of fuel, oil, cleaning materials, or human waste associated with equipment and the pumping of toilets.

Facilities, administration sites, and developed campgrounds provide public water supplies and restrooms. It is desired that recreation facilities and their use, including trails and dispersed sites, have minimal impacts on aquatic resources, including threatened and endangered species, designated critical habitat, and aquatic species of conservation concern (FW-DC-ARREC-01).

To protect water resources the Land Management Plan includes guidance in all action alternatives that directs new and reconstructed solid and sanitary waste facilities not be located within 100 feet of water, unless no other alternative exists (FW-GDL-ARREC-01) and that new developed recreation facilities avoid being placed in riparian management zones (FW-GDL-ARREC-02). The Land Management Plan also includes an objective to relocate or mitigate dispersed camp sites that are currently located within riparian management zones that have documented degradation of aquatic or riparian resources (FW-OBJ-ARREC-01).

Non-motorized trails typically have very little impact on water resources. Sediment from trails generally gets routed onto the forest floor with no impact to water quality. However, there are locations where sediment is routed to streams at crossings. These are temporary, localized impacts, which would not result in watershed scale impacts. The Land Management Plan includes plan components to reduce sediment delivery from trails (FW-GDL-ARREC-03, FW-GDL-ARREC-04, FW-GDL-ARREC-05, FW-GDL-ARREC-06) and objectives to maintain trails (FW-OBJ-REC-01, FW-OBJ-REC-02).

Contamination by petroleum products, such as motor oil and gasoline, may degrade water quality in waters adjacent to areas of concentrated use, such as developed recreation sites, parking lots, and snowmobile staging areas. These impacts are generally low as sites are relatively small in area and widely dispersed. Best management practices are used by the Nez Perce-Clearwater to ensure risk to soil and water resources is minimized.

See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to recreation management for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

System Roads and Motorized Trails Management

Roads and motorized trails is an indicator assessed in the watershed condition classification process (U.S. Department of Agriculture 2011d). This indicator addresses changes to the hydrologic and sediment regimes due to the density, location, distribution, and maintenance of the road and trail network. Attributes of this indicator include open road density, road and trail maintenance, proximity to water, and mass wasting. Based on the Nez Perce-Clearwater 2011 classification, 63 percent of the subwatersheds were rated as ‘Functioning at Risk’ (Class 2) or ‘Impaired’ (Class 3) for this indicator. For these subwatersheds, the density and distribution of roads and linear features indicates that there is a higher probability that the hydrologic and sediment regimes are considerably altered. See Appendix K for more information on watershed condition class related to roads and trails.

As stated in the watershed condition classification technical guide (Potyondy and Geier 2011):

Roads affect watershed condition because more sediment is contributed to streams from roads and road construction than any other land management activity. Roads directly alter natural sediment and *hydrologic regimes by changing streamflow patterns and amounts, sediment loading, transport, deposition, channel morphology and stability, and water quality and riparian conditions within a watershed (Copstead 1997, Dunne and Leopold 1978, Gibbons and Salo 1973). Road maintenance can also increase sediment routing to streams by creating areas prone to surface runoff, altering slope stability in cut-and-fill areas, removing vegetation, and altering drainage patterns (Burroughs and King 1989, Luce and Black 2001, Megahan 1978, Reid and Dunne 1984). Road density is known to play a dominant role in human-induced augmentation of sediment supply by erosion and mass wasting in upland forested landscapes in the Pacific Northwest (Cederholm et al. 1980, Furniss et al. 1991), and it is reasonable to assume that similar relationships exist elsewhere. Road-related mass soil movements can continue for decades after roads have been constructed, and long-term slope failures frequently occur after road construction and timber harvest (Megahan and Bohn 1989).*

The Impacts from motorized trails are similar as those from roads. The most notable impact is trail erosion and rutting, which can concentrate water flow and lead to sediment delivery to streams.

Effects in Common Across Action Alternatives

Desired conditions for roads are that the transportation system has minimal impacts on aquatic and riparian conditions through reduced hydrologic connectivity of roads to streams, lower sediment delivery to streams, reduced road impact to floodplains, and improved aquatic organism passage, where transportation infrastructure affects these features (FW-DC-ARINF-01); that the transportation network is resilient to the effects of climate change, including the ability to accommodate increased runoff and peak flows that may exceed historic streamflow events (FW-DC-ARINF-02); and that roads in the Conservation Watershed Network present minimal risk to aquatic resources (FW-DC-CWN-03). Desired conditions for trails are that trails have minimal impacts on aquatic resources (FW-DC-ARREC-01).

To move towards these desired conditions, objective FW-OBJ-INF-01 aims to **c**omplete 600 miles of road work under the Preferred Alternative Table 118, such as reconstruction, re-routing, road improvements, decommissioning, or placing roads in intermittent stored service, every 5 years. Priorities shall include reducing effects on desired aquatic and riparian conditions from chronic sediment delivery or potential future road prism failures, including previously decommissioned roads where drainage features have failed. From 2013 to 2022, the Nez Perce-Clearwater reconstructed and decommissioned an average 95 miles of system road annually. Over the 5-year period from 2018 to 2022, approximately 500 miles of system road was reconstructed and 13 miles of system road was decommissioned. Objective FW-OBJ-INF-02 aims to annually maintain 1,400 miles of operational maintenance level two through five roads under the Preferred Alternative (Table 118). From 2013 to 2022, the Nez Perce-Clearwater maintained an average annual 1,100 miles of operational maintenance level two through five roads.

Additionally, objectives for trail system management aim to annually maintain to standard a minimum of 30 percent of National Forest System trail miles (FW-OBJ-REC-01) and reduce deferred maintenance of trails by five percent, every five years (FW-OBJ-REC-02). From 2013 to 2022, the Nez Perce-Clearwater annually maintained to standard an average 34 percent of National Forest System trail miles and annually improved an average 44 miles of National Forest System trail miles.

Numerous standards and guidelines are proposed to limit the amount of sediment delivery or alteration of hydrologic flow regime from roads and trails, including limits on sidecasting of road material or snow (FW-STD-ARINF-03, FW-GDL-ARINF-07); routing road drainage away from streams and unstable slopes (FW-GDL-ARINF-09, FW-GDL-ARINF-02); requiring upgrading or removal of stream crossings (FW-STD-ARINF-04, FW-GDL-ARINF-03, FW-GDL-ARINF-05, FW-GDL-ARINF-11, FW-GDL-ARREC-03); avoiding high mass wasting potential areas and wetland areas (FW-GDL-ARINF-04, FW-GDL-ARINF-08, FW-GDL-ARREC-04); and hardening of stream crossings (FW-GDL-ARINF-06, FW-

GDL-ARREC-06). Standard FW-STD-ARINF-07 requires that when constructing or reconstructing roads in the Conservation Watershed Network and HUC12 subwatersheds with Endangered Species Act critical habitat or listed aquatic species, projects shall result in a net decrease in the hydrologic connectivity of the road system and stream channel network.

Effects That Vary by Alternatives

Under the No Action Alternative, road maintenance would be expected to continue at similar levels or slightly decreased levels due to declining budgets. Portions of the road network would be treated to repair and improve drainage structures, improve the running surface of the road, and to clear vegetation along roadsides. Short-term increases of sediment delivery to streams and waterbodies would be expected as a result of road surface grading, and culvert and ditch cleaning near waterbodies. Portions of the road system that are in particularly poor condition or are currently closed and in long-term storage would be reconstructed periodically, particularly in connection with land management activities, such as timber harvest projects. Best management practices would be employed to minimize erosion and sediment transport to waterbodies.

The Land Management Plan includes objectives to maintain, improve, stormproof, or reconstruct system roads. As discussed in the Infrastructure section of this Final Environmental Impact Statement, increased log-haul multiplies the amount of aggregate breakdown. When this occurs near streams, the potential for sediment delivery is higher. Proposed road reconstruction and improvements (FW-OBJ-INF-01) are proportional to the rate of increase in proposed timber harvest. Road reconstruction includes application of surface rock, replacing damaged or poorly functioning culverts, adding stream-crossing or ditch relief culverts where necessary, road template widening as needed, and removing roadside vegetation that is encroaching on the road surface. Miles of road maintenance (FW-OBJ-INF-02) and storm proofing of roads (FW-OBJ-CWN-02) also increase by alternative, proportional to the level of proposed timber harvest. Log-haul traffic under Alternative Z would be similar to the existing levels found under the No Action Alternative. Alternatives W, X, and Y and the Preferred Alternative have a higher risk of impact due to the amount of log-haul associated with the proposed timber harvest.

Although the Action Alternatives have the potential to increase sediment delivery to stream courses as a result of increased truck traffic associated timber harvest, this concern could be avoided or mitigated through development and implementation of project design features, timber sale contract provisions, and best management practices during project planning and implementation. Future road building would likely be confined to realignment or relocation, although new roads could be constructed to reach currently inaccessible areas. The road system, including miles, management level, and location is the same for all alternatives; however, road use would vary by alternative

See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to infrastructure for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

Land Ownership and Land Uses

The forest issues a variety of permits for projects under the lands and special uses programs. Forest Service permits can lead to interrelated and interdependent effects on private lands that are enabled by issuing a road use permit or right-of-way grant. It is assumed that temporary and short-term impacts could occur where special uses are allowed or mandated. Management activities that result in ground disturbance near streams and other bodies of water have the potential to affect water quality. These potential increases are based on site-specific factors such as slope, soil types, proximity to waterbodies, residual ground cover, and revegetation. Additionally, soil erosion, sediment delivery, and turbidity can increase due to heightened road activity from issuance of road use permits or granting rights-of-way. Road-related effects are discussed in the road and motorized trail section below.

Proposed standard FW-STD-ARLND-01 requires when authorizing new lands special uses, or reauthorizing existing uses, include conditions to avoid adverse effects to fish, water, and riparian resources. If adverse effects are unavoidable to Endangered Species Act listed fish, species of conservation concern, impaired water bodies, or stream habitat conditions, authorizations shall require actions that result in the re-establishment, restoration, mitigation, or improvement of conditions and ecological processes to ensure that projects that degrade conditions also include measures to improve conditions to the extent practicable. These processes include in-stream flow regimes, physical and biological connectivity, water quality, and integrity and complexity of riparian and aquatic habitat.

New hydropower support facilities would be located outside of riparian management zones to reduce effects to fish, water, and riparian resources (FW-STD-ARLND-02). If existing hydropower support facilities are located within riparian management zones at the time of permit reissuance guideline FW-GDL-ARLND-01 impacts to be reduced on aquatic and riparian resources, such as moving support facilities outside of riparian management zones or further from water bodies where feasible.

Permitted power and telephone line construction and maintenance would continue under all alternatives. Clearing brush and trees in riparian areas may increase solar radiation to streams and the forest floor, increasing water temperature. Limbing, topping, or removal of hazard trees near utility lines can also reduce in-channel wood. Power and telephone line corridor maintenance could result in loss of riparian vegetation where they cross or are adjacent to the stream network. The permitting process for new authorizations would look at options to minimize this effect.

Effects would be the same under all alternatives because the plan components under the Action Alternatives are generally the same as PACFISH and INFISH standards and guidelines under the No Action Alternative, with the exception of reauthorizations. See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to lands and special uses for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

Ecosystem Services Management

Ecosystem services are the benefits the National Forests provide to area residents, visitors, and the American public. Ensuring ecosystem services are provided is critical to providing for ecologic, social, and economic sustainability. The Land Management Plan includes desired condition FW-DC-ES-01 that promotes the Nez Perce-Clearwater's ability to provide ecosystem services to area residents and visitors. Key benefits the Nez Perce-Clearwater provides include clean water; clean air; wood products, including timber and firewood; forage; hunting, trapping and fishing; fish; cultural values, including heritage values, subsistence food gathering, and spiritual and inspirational values; scenery; recreation; and flood control and soil stabilization.

Guideline FW-GDL-ES-01 specifies that to provide for social and economic sustainability of rural communities, access to activities such as recreation, hunting, fishing, gathering, egress, and wildfire management should continue to be provided for on routes or in areas designated as open to motorized use in the summer and winter. If a route is identified as adversely affecting aquatic ecological values, rerouting and route improvement should be considered prior to closure, to preserve motorized access opportunities. If a route or area needs to be closed, alternate motorized access to maintain social and economic sustainability of rural communities should be provided.

This guideline could increase potential effects to water resources by limiting the ability to close or decommission system roads, as the focus of the plan component is to preserve motorized access opportunities. The amount and location of roads and trails were the major cause for subwatersheds to be classified as functioning at risk or having impaired function when rated using the watershed condition classification process. System roads generally have notable impact to riparian and wetland conditions and floodplain function on the Nez Perce-Clearwater. Out of the 7,682 miles of Forest Service system roads, 1,600 miles of road or approximately 6,400 acres occur within riparian management zones. Approximately 686 miles of road or 2,700 acres are located within 100 feet of stream channels and wetlands. Some of these road miles are continuous along substantial lengths of a stream channel or are unconnected sections of road that interact with streams only at stream crossings.

Under this guideline, if roads are decommissioned for adversely affecting aquatic ecological values, alternative access should be provided. This is not necessarily replacement mile for mile. Water resource conditions could still trend towards desired conditions if roads located within riparian management zones or mass movement areas are relocated or decommissioned and alternative routes are located on more stable areas, away from riparian areas. Hydrologically disconnecting roads (FW-STD-ARINF-07), storm proofing roads (FW-OBJ-CWN-02), annually maintaining 1,400 miles of operational maintenance level two through five roads (FW-OBJ-INF-02), and completing 600 miles of road work, such as reconstruction; re-routing; road improvements; decommissioning; or placing roads in intermittent stored service, every 5 years (FW-OBJ-INF-01) would also reduce impacts to water resources. Any new road construction to provide alternate motorized access would have to adhere to Aquatics and Riparian Infrastructure plan components and follow best management practices (FW-STD-WTR-02). The effects from ecosystem services management would be the same under all Action Alternatives.

Minerals Management

Historically, there have been hundreds of locatable mineral mining operations across the Nez Perce-Clearwater on both patented and unpatented mining claims. Impacts from historic mining are still evident across the Nez Perce-Clearwater. Placer and, to a lesser extent, lode mining have physically altered stream morphologies in much of the Palouse, Clearwater, Upper and Lower North Fork Clearwater, and South Fork River subbasins. Effects from historic mining was one of the leading causes for impairment to streams when the Nez Perce-Clearwater evaluated watershed conditions in 2011 using the watershed condition classification process. All seven of the subwatersheds identified as having impaired function included channel alteration and reduced water quality due to historic mining.

Recreational mining activities, such as panning, metal detecting, hand-sample collection, and the use of small-scale sluice systems, occur across the Nez Perce-Clearwater, particularly in areas of historic lode or placer mining activities. Unless an authorized officer determines that an activity is or will cause a significant disturbance to surface resources, a Plan of Operations is not likely to be required. The 1872 mining law allows for the development of locatable minerals, including gold and other minerals in streams. All locatable mineral activities are required to meet applicable environmental protection measures as required by both Federal and State laws, regulations, and policies. Proposed locatable mineral activities are subject to review and approval, as well as environmental analysis and reclamation and monitoring requirements. Mining activities are restricted in many rivers within the Nez Perce-Clearwater by the Idaho Comprehensive State Water Plan (Idaho Department of Water Resources 2012). Mining that occurs within or adjacent to riparian areas and wetlands can reduce water availability and flow and increase sedimentation and/or other pollution. Dredge mining in streams can cause redistribution of fine sediment. As equipment dredges the stream bed, water flow immediately transports material downstream. Placer mining operations create disturbed areas large enough to gather streambed material, sort it, and deposit it. Loss of riparian vegetation through mining activities can increase sediment delivery and alter stream temperatures.

To protect water quality, riparian areas, and stream channels, the Land Management Plan proposes standards and guidelines that include the following: requirement of a reclamation plan and bond for mining activities in riparian management zones (FW-STD-AREM-01); limiting mine waste in riparian management zones (FW-STD-AREM-02); limiting mineral operations in riparian management zones unless strict adherence to guidance is followed (FW-GDL-AREM-01, FW-GDL-AREM-02); controlling water flow paths to maintain water quality and to prevent biological, chemical, or industrial pollutants from being delivered to water bodies (FW-GDL-AREM-03); and requiring the use of best management practices (FW-GDL-AREM-04). Standard FW-STD-EM-01 directs that new mineral and energy management activities shall only be authorized when the associated reclamation plan includes provisions to return disturbed areas to a state of site condition comparable to pre-mineral activity. Additionally, to minimize ground disturbance and sediment inputs, and avoid adverse effects to riparian vegetation and water temperature New saleable sand and gravel mining and extraction should not occur within riparian management zones (FW-GDL-RMZ-09).

The No Action Alternative also includes direction for minerals management. The Nez Perce and Clearwater forest plans, as amended by PACFISH, include standards and guidelines that are equivalent to the revised Land Management Plan, although they do not require a reclamation plan and bond for mining activities in riparian management zones. See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to minerals management for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

Livestock Grazing Management

The Nez Perce-Clearwater has 36 active range allotments occurring on 612,766 acres or approximately 15 percent of the Nez Perce-Clearwater. Some of the allotments are forested and considered transitory range. The Land Management Plan alternatives do not propose changes to allotment boundaries or level of use. Objective FW-OBJ-GRZ-01 is the same for all action alternative, projecting approximately 29,800 to 34,400 animal unit months per year. This is the same level of livestock grazing as the No Action Alternative.

Impacts to the water resource from livestock grazing are localized but tend to be highest near riparian and wetland areas. Impacts are often greater in riparian and meadow areas because they are preferred by livestock due to the availability of shade, water, and more palatable forage. The most notable impacts are reduced riparian and meadow vegetation and stream bank alteration at livestock trail crossings and watering sites, although the extent, severity, and locations are highly variable from year to year. Livestock grazing near streams can result in changes in channel morphology (Belsky et al. 1999). Livestock trailing, chiseling, and general soil displacement along stream bank areas can result in collapse of undercut bank areas and an overall increase in bank angle, loss of bank cover, and stream widening along the entire stream reach. Over long time periods, loss of riparian habitats may occur due to stream channel widening or degradation, and lowering of water tables through channel incision. In a few allotments, fences have been installed to exclude cattle from grazing and trampling banks within riparian zones or to protect sensitive areas, such as meadows.

The effects of historic livestock grazing are still evident, affecting riparian vegetation composition and stream channel form and function. Many of the allotments have seen improvements through best management practices, updated allotment management plans, and specific guidance in annual operating instructions. However, impacts to riparian and wetland area conditions within grazing allotments persist.

Annual indicators that can be used to monitor livestock grazing include within season or end of season stubble height, streambank alteration, woody species utilization, and extent of bare ground. When designed with and supported by best available science, annual indicators can provide a reasonable assurance that if they are consistently met, long-term desired condition attainment would be expected within reasonable timeframes. As such, they provide a short-term means of using adaptive management on an annual basis to meet or move toward the long-term desired conditions.

Under the Action Alternatives, existing grazing permits would continue to be administered under current allotment management plans; however, they would be required to meet or be moving towards desired conditions for riparian and meadow areas (FW-DC-GS-04, FW-DC-RMZ-01, FW-DC-RMZ-02) as outlined in the Land Management Plan. To address livestock grazing impacts and reduce the effects of grazing on water resources, the Land Management Plan includes standard FW-STD-ARGRZ-01, which requires monitoring and adjustment of grazing practices as necessary to promote desired conditions for riparian and meadow areas. Standard FW-STD-ARGRZ-02 specifies that where livestock trailing, bedding, watering, salting, loading, off road vehicle use for managing or gathering livestock, and other related activities in riparian management zones are adversely affecting aquatic resources, annual operating instructions shall include measures to mitigate or relocate to other areas or times. Guideline FW-GLD-ARGRZ-03 requires the protection of seeps and springs from livestock trampling at spring developments. Additionally, standard FW-STD-WTR-04 specifies that where aquatic and riparian desired conditions are being achieved, projects shall maintain those conditions; where aquatic and riparian desired conditions are not yet achieved, and to the degree that project activities would contribute to those conditions, projects shall restore or not retard attainment of desired conditions.

Streams with lower gradients are the most sensitive to livestock grazing impacts (Rosgen 1996). To maintain or improve riparian and aquatic conditions and achieve riparian desired conditions, proposed guideline FW-GDL-ARGRZ-01 establishes minimum end of season stubble heights of 10 to 15 centimeters (4 to 6 inches) along the greenline for low gradient streams.

Stubble height is a meaningful and relatively easily determined metric related to riparian vegetation and has been found to correlate with instream habitat quality (Roper 2020), and has been widely used as an end-of-season monitoring indicator (U.S. Department of Agriculture 2022e). End of season stubble height along the greenline has been shown to be a good indicator of two primary factors: 1) the effect of grazing on the physiological health of herbaceous, hydrophytic plants, and 2) the ability of the vegetation to provide streambank protection and bank building function.

Clary and Webster(1990) recommended that in the Intermountain West, a minimum stubble height of approximately 10 to 15 centimeters should remain at the end of the grazing season to maintain plant vigor and provide for bank protection and for sediments to be deposited. However, 19-20 centimeters stubble height was the optimal length to retain sediment deposits (Abt et al. 1994, Thornton et al. 1997). Similarly, Clary and Leininger (2000) indicated that 15-20 centimeters stubble height would be necessary to protect willow and vulnerable streambanks. Clary (1999) found that 10 centimeters protected most of the stream attributes while 14.1 cm was needed to protect all stream attributes. Higher average stubble height at the end of season is more likely to provide plants with enough growth during the season to retain vigor in the following season (Clary 1995, Boyd and Svejcar 2012).The proposed standards and guidelines in the Land Management Plan are designed to protect upland and riparian resources and provide overall guidance for managing livestock grazing within allotments. In addition, specific allotment management plans and/or annual operating plans provide instructions to grazing permittees designed to ensure adequate riparian and upland resource protection while providing for the sustainability of forage. These plans and the direction they contain are site specific for each allotment and are not part of this analysis.

The No Action Alternative would continue management of the grazing program under direction in the 1987 Forest Plans, as amended by PACFISH and INFISH. The direction requires modification of grazing practices that retard or prevent attainment of riparian management objectives or are likely to adversely affect listed anadromous fish. They also require that new livestock handling facilities be located outside of riparian habitat conservation areas and that livestock trailing, bedding, watering, salting, loading, and other handling efforts be limited to areas and times where they will not retard or prevent attainment of riparian management objectives. See Aquatic Ecosystems and Fisheries Effects of No Action Alternative vs Action Alternatives section related to livestock grazing for a direct comparison between PACFISH standards under the No Action Alternative and plan components from the Land Management Plan under the Action Alternatives.

Special Forest and Botanical Products

Firewood cutting in riparian areas has the potential to impact riparian function through reductions in thermal cover, large wood recruitment to streams, and ground disturbance. To limit the potential for impacts to riparian areas, standard FW-STD-RMZ-04 dictates that no fuelwood cutting within 150 feet of the stream edge would be authorized. This direction is also included in national firewood permits.

Designated Wilderness Management

Watershed conditions in designated wilderness areas were found to be functioning properly when watershed conditions were assessed in 2011. Ecological processes are within historical ranges and the resiliency of watersheds to recover from disturbances is high. The primary drivers of change in wilderness areas are wildfires, landslides, and insect and disease infestations. Changing climate may contributed to, and possibly exacerbate, the magnitude and extent of effects from these drivers. The management of designated wilderness benefits water resources under all alternatives. Natural processes would continue to drive watershed and water resource functions and conditions.

Designated Wild and Scenic Rivers Management

Three wild and scenic rivers have been designated on the Nez Perce-Clearwater – the Middle Fork Clearwater, which includes the Lochsa River and Selway River; the Main Salmon River; and Rapid River. Regulation ensures that water quality is maintained and, where possible, enhanced, and minimum flows are reserved to maintain a river's social and ecological values. Water rights are regulated in wild and scenic river drainages. All surface water rights, and ground water rights diverted from sources hydraulically connected to the wild and scenic river reaches upstream from the ending points are recorded, tracked, and administered as anticipated under the provisions of the Wild and Scenic Agreement. The area hydraulically connected to the wild and scenic river reaches covers 2,112,767 acres, or 52 percent of Nez Perce-Clearwater lands.

Designated wild and scenic rivers would receive the same or better level of protections under the Action Alternatives as compared to the No Action Alternative. For the Action Alternatives, standard MA1-STD-DWSR-02 requires management activities in designated wild and scenic river corridors to protect and enhance their free-flowing character, water quality and outstandingly remarkable values for which the river was designated.

Recommended Wilderness

Management direction for recommended wilderness would be beneficial to water resources under all the Action Alternatives because of the limitation of land management activities that most often directly impact water resources. The amount of recommended wilderness varies by alternative. Alternative X proposes no recommended wilderness. The Preferred Alternative identifies three recommended wilderness areas totaling 258,210 acres–Mallard Larkins, Hoodoo, and East Meadow Creek. Alternative W proposes the most wilderness areas, identifying ten areas, totaling 856,932 acres, followed by Alternative Z with 569,755 acres, and Alternative Y with 309,332 acres. Under the No Action Alternative, 197,695 acres have been managed as recommended wilderness since the 1987 plans were developed. Recommending these areas as wilderness would ensure that wilderness characteristics would be maintained. Under the Action Alternatives, management actions are already limited because they are all included in Idaho Roadless Rule areas. Therefore, the magnitude of the positive effects to water resources from the Action Alternatives relative to the No Action alternative are anticipated to be small. Natural processes would continue to drive watershed and water resource functions and conditions.

Eligible and Suitable Wild and Scenic Rivers

For all alternatives, identifying segments of rivers and streams that are eligible or suitable for wild and scenic river designation provide beneficial effects to water resources. Rivers found to be eligible or suitable for wild and scenic river inclusion would be managed to protect the river-related outstandingly remarkable values identified for the river and protect the free-flowing nature and quality of the water. These protection measures would be maintained until a decision is made on the future use of the river and adjacent lands through an Act of Congress or a determination that the river is not suitable for inclusion. Wild and scenic rivers are bounded by a corridor that extends one-quarter mile on each side of the river segment, measured from the high-water mark.

Under the Action Alternatives, to protect river values, standard MA2-STD-E&SWSR-01 limits the construction of roads, trails, facilities, or airstrips within the eligible or suitable river segment that would alter the classification of the river. Any new road, trail, and airfield construction would be designed to maintain the outstandingly remarkable values, classification, free-flowing character, and water quality of the river. Additionally, hydroelectric power facilities are not suitable in eligible or suitable wild and scenic rivers (MA2-SUIT-E&SWR-10). Within the riparian management zone directly adjacent to the eligible or suitable wild and scenic river, Aquatic Ecosystems plan components in the Land Management Plan, under all Action Alternatives, provide management direction that is more rigorous for water resources than direction in the Wild and Scenic Rivers Act. Wild and scenic river designation in the future could offer additional water resource benefits, such as the establishment of non-consumptive minimum stream flow water rights.

Summary of Environmental Consequences

A summary of the environmental consequences to water resource by alternative is presented in Table 120. Because desired conditions, standards, and guidelines for water and aquatic resources do not vary between Action Alternatives, any differences in the effects to water resources would be based on the potential positive movement towards desired conditions through implementation of aquatic ecosystem objectives compared to the potential increased risk to water resources from the movement towards desired conditions for other resources. Overall, the desired conditions for the terrestrial and aquatic ecosystem resource areas are integrated and encourage maintaining or improving ecosystem resilience and ecological integrity.

The 2012 Planning Rule requires that National Forests provide for social, economic, and ecological sustainability within Forest Service authority and consistent with the inherent capability of the plan area (36 CFR 219.8). The 2012 Planning Rule also requires that a plan include plan components including standards or guidelines, for integrated resource management to provide for ecosystem services and multiple use (36 CFR 219.10(a)). To achieve that balance, there could be a potential continued or increased risk to water resources. These potential risks to water resources would primarily occur in Management Marea 3. Standards and guidelines for management actions that could affect water resources are included in the Land Management Plan to help achieve or maintain aquatic ecosystem desired conditions, to avoid or mitigate undesirable effects, or to meet applicable legal requirements. The potential benefit from increased restoration and potential risk from management resources varies by Action Alternative and are all greater than what would occur under the No Action Alternative.

Table 120. Summary of consequences to water resources by alternative (Alt)

Measurement Indicator	No Action	Alt W	Alt X	Alt Y	Alt Z	Preferred
Watershed Condition Rate of improvement in Hydrologic Unit Code (HUC) 12 subwatersheds using the watershed condition framework	Low	Highest	Highest	High	Moderate	High
Water Quality Potential risk to water quality Potential benefit from restoration	Moderate	High	Highest	High	Moderate	High
Water Quantity Potential risk to water quantity Potential benefit from restoration	Moderate	High	Highest	High	Moderate	High
Riparian areas, wetlands, and floodplain function Potential risk Potential benefit from restoration	Moderate	High	Highest	High	Moderate	High

Conclusion

The Land Management Plan must include plan components to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity (36 CFR 219.8(a)(1)).

The Land Management Plan identifies five "in progress" priority watersheds that are a priority for maintenance or restoration (36 CFR 219.7(f)(1)(i)) and provides guidance for the establishment of additional priority watersheds through the life of the plan.

The Land Management Plan includes plan components that emphasize the maintenance or improvement of water quality (36 CFR 219.8(a)(2)(iii)) and includes a plan component to ensure implementation of national best management practices for water quality (36 CFR 219.8(a)(4)).

The Land Management Plan includes plan components that promote the maintenance or restoration of water resources in the plan area, including lakes, streams, and wetlands; ground water; public water supplies; source water protection areas; and other sources of drinking water, including guidance to prevent or mitigate detrimental changes in water quantity, quality, and availability (36 CFR 219.8(a)(2)(iv)).

The Land Management Plan includes plan components to maintain or restore the ecological integrity of riparian areas in the plan area, including plan components to maintain or restore structure, function, composition, and connectivity (36 CFR 219.8(a)(3)(i)). The Plan also establishes riparian management zone widths around all lakes, perennial and intermittent streams, and open water wetlands, giving special attention to land and vegetation for approximately 100 feet from the edges of all perennial streams and lakes (36 CFR 219.8(a)(3)(ii)).

The Land Management Plan provides a broad spectrum of standards and guidelines designed to protect soil, water, riparian, and aquatic resources. The goals and intent of Executive Orders 11988 (Floodplain Management) and 11990 (Protection of Wetlands) would be met through compliance with the Land Management Plan direction.

The Land Management Plan contains plan components for integrated resource management to provide for ecosystem services and multiple use [including watershed] (36 CFR 219.10(a)), including plan components to maintain or restore riparian areas and surface and subsurface water quality (§219.10(a)(1)) and public water supplies and associated water quality (§219.10(a)(9)).

3.2.8 Aquatic Ecosystems and Fisheries

Chapter 3 presents the existing environment of the areas used for analysis and the potential consequences to that environment that may be caused by implementing the alternatives described in Chapter 2. The following discussion of resources and potential effects draws on existing information included in the Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a), other planning documents, resource reports and related information, and other sources, as indicated. In addition, in 2018, an interagency and partner working group (Aquatic and Riparian Conservation Strategy) was convened that brought significant amounts of information from partners and other reg agencies. The planning record contains additional references not listed in the reference sections of the Final Environmental Impact Statement and appendices. This section considers numerous physical and biological resources associated with riparian and aquatic habitats, including aquatic species.

Changes between draft and final

Comments received since the proposed action and Draft Environmental Impact Statement were published have been used, where appropriate, to improve the Land Management Plan and have helped inform this Final Environmental Impact Statement. Multiple changes were made for the Final Environmental Impact Statement; all changes are within the scope of the Draft Environmental Impact Statement analysis and address issues that the public had an opportunity to comment on. With respect to aquatic ecosystems and fisheries, there were changes to Affected Environment section to update status descriptions using new or more accurate data and information. In addition, changes were made to the draft Species of Conservation Concern list (with the Forest Service recommendation omitting Clearwater spring and summer Chinook, editing rationale for other species) because a review of the list and the criteria for that list found that changes were warranted. In addition, more analysis was added for plan direction that differs by alternatives. In addition, there were changes to the Aquatic Ecosystems plan components and Wildlife plan components that were driven from commenters and internal Forest Service suggestions. Also, as a result of public input, an additional alternative was developed, called the Preferred Alternative. Analysis of the Preferred Alternative for aquatic ecosystems and fisheries is similar to all action alternatives.

Relevant Laws, Regulations, and Policy

Federal Laws

National Environmental Policy Act of 1969

The National Environmental Policy Act of 1969 requires federal agencies to incorporate environmental considerations in their planning and decision-making through a systematic interdisciplinary approach. Specifically, all federal agencies are to prepare detailed statements assessing the environmental impact of and alternatives to major federal actions significantly affecting the environment (1969).

Endangered Species Act of 1973, as amended

Endangered Species Act (ESA) of 1973, as amended: Section 7(a)(1) supports biotic sustainability by requiring that "all federal agencies shall . . . utilize their authorities in furtherance of the purposes of the ESA, and cooperate with state and local agencies to resolve water resource issues in concert with conserving endangered species.

Section 7(a)(2) includes direction that federal agencies, in consultation with the U.S. Fish and Wildlife Service, will not authorize, fund, or conduct actions that are likely to jeopardize the continued existence of any threatened or endangered species or result in the destruction or adverse modification of their critical habitat. This is accomplished by formal consultation with the U.S. Fish and Wildlife Service and National Marine Fisheries Service in cases where ESA listed species or critical habitat are present and may be affected by federal agencies' actions. This pertains to project level activities, as well as forestwide activities like plan revision, or forest or region wide programmatic consultations. In the case of the revised forest plan, consultation is underway, and the ensuing Biological Opinion will supersede any previous Biological Opinions pertaining to forest plans.

Multiple Use Sustained Yield Act of 1960

Multiple-Use Sustained-Yield Act of 1960: Congress has affirmed the application of sustainability to the broad range of resources over which the Forest Service has responsibility. The Multiple-Use Sustained-Yield Act confirms the Forest Service's authority to manage the national forests and grasslands "for outdoor recreation, range, timber, watershed, and wildlife and fish purposes" (16 U.S.C. § 528) and does so without limiting the Forest Service's broad discretion in determining the appropriate resource emphasis or levels of use of the lands of each national forest and grassland.

Magnuson-Stevens Act of 1976, as amended

The Magnuson-Stevens Act of 1976 (16 U.S.C. 1801 et seq.) (MSA) is the primary law that governs marine fisheries management in United States federal waters. It is intended to foster the long term biological and economic sustainability of marine fisheries. It is primarily concerned with regulating commercial fisheries and preventing overfishing. It established federal waters as spanning 200 miles offshore of the United States and established regional fishery management councils. One important provision of the Act is an objective to "protect habitat that fish need to spawn, breed, and grow to maturity." The Act was reauthorized in 1996 with the Sustainable Fisheries Act of 1996 (63 FR 24212), which added a requirement for fishery management councils to identify and describe "Essential Fish Habitat" (EFH). The provision for EFH was revised in 2002 (67 CFR 2343) allowing fishery management councils to designate Habitat Areas of Particular Concern and established a federal consultation process for agencies working in EFH areas. The Act was reauthorized with the MSA Reauthorization Act of 2006, and again amended with the Modernizing Recreational Fisheries Management Act of 2018.

National Forest Management Act of 1976

National Forest Management Act of 1976: This act directs the Forest Service to manage for a diversity of habitats to support viable populations (36 CFR § 219.19). Regulations further state that the effects on these species and the reasons for their choice as management indicator species need to be documented (36 CFR § 219.19(a)(1)).

Idaho Roadless Rule

The Idaho Roadless Rule (36 CFR § 294.29, as amended) established roadless areas and established five management classifications that provided management direction and constraints across a continuum (these classifications are often referred to as themes), including Wildland Recreation; Special Areas of Historic or Tribal Significance; Primitive; Backcountry/Restoration; and General Forest, Rangeland, and Grassland.

Agency Regulations

The Nez Perce-Clearwater supports five fish species currently listed as threatened or endangered under the Endangered Species Act (ESA) and contains designated critical habitat for these species. The last two decades history of listings related to the ESA is complicated. In Idaho, in the 1990s, sockeye salmon (*onchorynchus nerka*), steelhead (*onchorynchus mykiss*), and two stocks of Chinook (*onchorynchus tsawytscha*) salmon were listed under the ESA, in addition to bull trout (*salvelinus confluentus*). Snake River spring and summer Chinook salmon were listed threatened in the Salmon River subbasin on April 22, 1992 (57 FR 14653), and critical habitat was designated on October 25, 1999 (64 FR 57399). Snake River fall Chinook salmon were listed threatened on April 22, 1992 (57 FR 14653), and critical habitat was designated December 28,1993 (58 FR 68543). Snake River sockeye salmon were listed endangered on November 20, 1991 (56 FR 58619), and critical habitat was designated on December 28, 1993 (58 FR 68543). Snake River steelhead were listed threatened on August 18, 1997 (62 FR 43937), with critical habitat designated September 2, 2005 (70 FR 52629). These species are present on the Nez Perce-Clearwater, although in the case of sockeye salmon no spawning or rearing occurs on the Nez Perce-Clearwater. Bull trout were listed threatened throughout the United States on November 1, 1999 (64 FR 58910), and critical habitat was designated on October 6, 2004 (69 FR 59995). The U.S. Fish and Wildlife Service (USFWS) released a bull trout recovery plan (U.S. Department of the Interior 2015c) and Recovery Unit Implementation Plans for the Mid-Columbia and Upper Snake Recovery Areas (U.S. Department of the Interior 2015a, d), which include portions of the Nez Perce-Clearwater. In addition, range-wide consultation on bull trout critical habitat with the USFWS occurred in 2018 (U.S. Department of the Interior 2018a) that included the streams on the Nez Perce-Clearwater National Forest.

National Oceanic and Atmospheric Administration Fisheries Recovery Plans

Snake River Spring/Summer Chinook and Steelhead Recovery Plan

Snake River Recovery Plan (Snake River Basin Steelhead and Snake River Spring/Summer Chinook Salmon): The National Marine Fisheries Service has released final recovery plans for Snake River spring and summer Chinook salmon and steelhead in 2017 (National Oceanographic and Atmospheric Agency 2017). Prior to recovery planning, the National Oceanic and Atmospheric Administration Fisheries, also known as the National Marine Fisheries Service (NMFS), conducted broad-scale consultations on Land Management Plans, as amended by PACFISH. As part of programmatic consultations with the Forest Service and Bureau of Land Management, the NMFS issued two Biological Opinions – one in 1995 for Snake River salmon and another in 1998 for Snake River salmon and steelhead. Consultations with the NMFS resulted in direction above and beyond that which is contained in PACFISH, including but not limited to the addition of two sediment Riparian Management Objectives, adoption of nine conservation measures for listed steelhead, enhanced direction for watershed analysis, and expansion of the “key” watershed concept to all Interior Columbia River Basin watersheds within the range of listed steelhead. This direction was intended to apply until forest plans were revised.

The 2017 Snake River Recovery Plan is comprised of nine chapters and includes an implementation framework. Appendix C: Idaho Management Unit Plan is specific to Idaho spring and summer Chinook salmon and steelhead populations (National Oceanographic and Atmospheric Agency 2017). The recovery plan identifies populations and geographic locations within each major population group of listed steelhead and spring and summer Chinook salmon, along with a summary of threats and limiting factors. Portions of these geographic areas, including large percentages for the Clearwater steelhead major population group and smaller percentages of the Salmon River major population group, are on the Nez Perce-Clearwater. The Clearwater steelhead major population group includes Lolo Creek, the Lower Mainstem Clearwater River, the Lochsa River, the Selway River, and the South Fork Clearwater River. The Salmon River major population group includes the Little Salmon River and Chamberlain Creek. For each of these populations, habitat limiting factors and improving actions are identified. Areas where focused habitat restoration is a priority are identified for each population. The draft recovery plan also identified major and minor spawning areas within each population area.

The plan includes a framework for achieving implementation of the plan that builds on and enhances partnerships.

Snake River Fall Chinook Recovery Plan

National Oceanic and Atmospheric Administration Fisheries released a final recovery plan for Snake River Fall Chinook Salmon in 2017 (National Oceanic and Atmospheric Administration 2017) It identifies one major population group (MPG) consisting of the extant Lower Snake River population and the extirpated Middle Snake population. The recovery plan identifies geographic locations within the existing major population group, along with a summary of threats and limiting factors, and identifies five major spawning areas (MaSA) to include Upper Hells Canyon, Lower Hells Canyon, Clearwater River, Grande Ronde River, and Tucannon River. Most of these geographic areas are outside the boundaries of the Nez Perce-Clearwater National Forest. The Clearwater MaSA includes the Clearwater River up to its confluence with Lolo Creek, and the Upper Hells Canyon MaSA includes the lower mainstem Salmon River as a dependent tributary. For this population, habitat limiting factors and improving actions are identified. Areas where focused habitat restoration is a priority are identified for each population.

Snake River Sockeye Recovery Plan

National Oceanic and Atmospheric Administration Fisheries released a final recovery plan for Snake River Sockeye Salmon in 2015 (National Oceanic and Atmospheric Administration 2015). It identifies one MPG, the Sawtooth Valley Lakes group. Within this MPG are one extant population and four extirpated populations. The recovery plan identifies geographic locations within the existing major population group, along with a summary of threats and limiting factors, and identifies one extant MaSA to include Redfish Lake, and from two to four extirpated historical populations, all of which occur on an adjacent national forest. The mainstem Salmon River, which forms the southernmost boundary of the Nez Perce-Clearwater National Forest, was identified as a migrations corridor for sockeye.

United States Fish and Wildlife Service

Columbia River Bull Trout Recovery Plan

Columbia River Bull Trout Recovery Plan and Recovery Unit Implementation Plans: The Columbia River bull trout recovery plan was completed in 2015. Recovery actions were developed in cooperation with federal, state, tribal, local, and other partners and generally fall into four categories:

1. Protect, restore, and maintain suitable habitat conditions for bull trout.
2. Minimize demographic threats to bull trout by restoring connectivity or populations, where appropriate, to promote diverse life history strategies and conserve genetic diversity.
3. Prevent and reduce negative effects of non-native fishes and other non-native taxa on bull trout.
4. Work with partners to conduct research and monitoring to implement and evaluate bull trout recovery activities consistent with an adaptive management approach using feedback from implemented, site-specific recovery tasks and considering the effects of climate change.

Streams and lakes on the Nez Perce-Clearwater are included in two Recovery Unit Implementation Plans – the Mid-Columbia and Upper Snake (U.S. Department of the Interior 2015a, d).

Recovery and conservation actions for the Clearwater basin, which is part of the Mid-Columbia Recovery Unit Implementation Plan, include changes to upland and riparian land management practices, including reduction of fine sediment production and stabilization of roads, road stream crossings, landslides, and other known sources of sediment delivery. There are specific objectives and priorities identified for many subwatersheds on the Nez Perce-Clearwater. Recovery and conservation actions for the Salmon basin, which is part of the Upper Snake Recovery Unit Implementation Plan, are similar.

Policy

FSM 2670: As an implementing rule of the 1976 National Forest Management Act, FSM 2670 requires federal land managers to maintain viable populations of all native and desirable non-native species, with special care taken to assure that federally listed species are allowed to recover. Actions that may cause a species to become listed as threatened or endangered are to be avoided.

PACFISH or INFISH Amendments: In the early 1990s, concerns about stream habitat degradation in the western United States, as well as the potential loss of salmon, trout, and char populations, increased (Nehlsen et al. 1991, Rieman and McIntyre 1993). In response, the Forest Service and Bureau of Land Management completed three broad reaching documents that amended forest plans across the west to improve their conservation function. PACFISH and INFISH were designed to maintain options for anadromous and inland native fish by reducing negative impacts to aquatic habitat. Riparian management objectives, standards, guidelines, and monitoring requirements were implemented beginning in 1995 to avoid causing further damage and begin recovery of aquatic habitats. All forest plans in the Forest Service Northern Region were amended by either PACFISH or INFISH in 1995, and this strategy is still in effect on all National Forests that have yet to update their plans. The Clearwater Forest Plan was amended by both PACFISH and INFISH.

PACFISH and INFISH were originally expected to last 18 months to three years. An effort similar to the Northwest Forest Plan, the Interior Columbia Basin Ecosystem Management Project (U.S. Department of Agriculture and U.S. Department of the Interior 2014a), was completed for the Interior Columbia River Basin. That effort acts in the form of guidance for plan revisions occurring in areas covered by PACFISH and INFISH. Interior Columbia Basin Ecosystem Management Project science and guidance has been used to guide this plan. In addition, this plan also follows direction in the 2012 Planning Rule. Specifically, greater emphasis is placed on meeting improved and more refined desired conditions. "Standards and guidelines" that were not differentiated in PACFISH and INFISH are separated into standards or guidelines in this plan. Objectives as occurring in PACFISH or INFISH have been replaced by Desired Conditions and some indicators that had objectives are not monitored for improvement.

Record of Decision for Amendments to Forest Service and Bureau of Land Management Land Planning Documents Within the Range of the Northern Spotted Owl, often referred to as the Northwest Forest Plan Record of Decision (U.S. Department of Agriculture 1994). Both the Northwest Forest Plan and PACFISH greatly improved protection for migratory salmon and steelhead.

Decision Notice and Decision Record for Interim Strategies for Managing Anadromous Fish-Producing Watersheds on Federal Lands in Eastern Oregon, Washington, Idaho, and Portions of California (U.S. Department of Agriculture and U.S. Department of the Interior 1995a); referred to as PACFISH

Inland Native Fish Strategy-Interim Strategies for Managing Fish-Producing Watersheds in Eastern Oregon, Washington, Idaho, Western Montana, and Portions of Nevada (U.S. Department of Agriculture 1995d); referred to as INFISH

Memorandum on Restoring Healthy and Abundant Salmon, Steelhead, and Other Native Fish Populations in the Columbia River Basin (Sep 7, 2023): This memorandum sets forth the following language as the policy:

Section1. Policy. It is a priority of my Administration to honor Federal trust and treaty responsibilities to Tribal Nations — including to those Tribal Nations harmed by the construction and operation of Federal dams that are part of the Columbia River System (CRS) — and to carry out the requirement of the Pacific Northwest Electric Power Planning and Conservation Act (Public Law 96-501) to operate, manage, and regulate the CRS to adequately protect, mitigate, and enhance fish and wildlife affected by the Federal dams in the Basin in a manner that provides equitable treatment for fish and wildlife with the other purposes for which the Federal dams are managed and operated.

In recognition of these priorities, it is the policy of my Administration to work with the Congress and with Tribal Nations, States, local governments, and stakeholders to pursue effective, creative, and durable solutions, informed by Indigenous Knowledge, to restore healthy and abundant salmon, steelhead, and other native fish populations in the Basin; to secure a clean and resilient energy future for the region; to support local agriculture and its role in food security domestically and globally; and to invest in the communities that depend on the services provided by the Basin's Federal dams to enhance resilience to changes to the operation of the CRS, including those necessary to address changing hydrological conditions due to climate change.

It also includes instructions to federal agencies regarding implementation, and directs federal agencies to use their authorities and available resources to further the policy found in Section 1.

State and Local Plans

State of Idaho

Idaho Department of Fish and Game

Idaho Department of Fish and Game 5 Year Fisheries Management Plan

Idaho Department of Fish and Game (IDFG) Five-year Fisheries Management Plan (Idaho Department of Fish and Game 2019b) (2019–2024): This management plan includes statewide principles related to management of fisheries and habitat; public involvement; rules such as fishing regulations; access; importation and introductions; cooperation with other agencies, Indian Tribes, outfitters, and guides; habitat restoration and protection; and mitigation. The IDFG has completed a specific management plan to conserve westslope cutthroat trout (*Onchorynchus clarki lewisii*) (2013b) and includes a goal of completing one for interior redband trout. In 2016, the Interior Redband Conservation Team (IRCT), comprised of multiple states, tribes, federal agencies, and Trout Unlimited, completed a document entitled "Conservation Strategy for Interior Redband (*Oncorhynchus mykiss* subsp.) in the States of California, Idaho, Montana, Nevada, Oregon, and Washington" (Interior Redband Conservation Team 2016) addressing redband throughout their range.

Specific to bull trout, the IDFG 5-year management plan states that the IDFG will continue to work closely with the U.S. Fish and Wildlife Service and other stakeholders on bull trout conservation and recovery planning and will advocate for de-listing those portions of the range where bull trout populations are secure and no longer in need of Endangered Species Act (ESA) protection. Additionally, they note that ongoing coordination with federal land management agencies, such as the Forest Service, is critical due to their large span of control over much of the bull trout habitat in Idaho.

The IDFG management plan also includes specific management principles to guide high mountain lakes, fish stocking within those lakes, and management of native amphibians.

For anadromous fish in Idaho, the IDFG management plan has outlined escapement goals at Lower Granite Dam for salmon and steelhead that exceed minimum abundance thresholds established in recovery plans for salmon and steelhead stocks listed under the ESA. Escapement goals identified by the management plan identify the number of adult salmon and steelhead needed to seed spawning habitat, provide directed harvest opportunity, and accommodate conservation and supplementation hatchery programs where currently implemented. Referred to as "healthy and harvestable," these escapement goals extend beyond the minimum abundance thresholds adopted in the ESA recovery plans to consider fish for delisting (National Oceanic and Atmospheric Administration 2016). The minimum abundance thresholds targets are minimum targets related to long-term extinction risk and do not provide sufficient escapement for full habitat seeding, nor do they reflect reasonable harvest opportunity.

Spring and summer Chinook salmon in the Clearwater basin are not listed under the ESA and escapement goals for them are not included in Snake River recovery plans. They are included in the IDFG escapement goals.

In addition, the IDFG management plan identifies geographic locations for emphasis of wild-origin summer steelhead and spring and summer Chinook salmon, which includes the Lochsa, Selway, and Potlatch rivers in the Clearwater Basin, Rapid River in the Lower Little Salmon subbasin, and tributaries to the Salmon River from the mouth upstream to the Middle Fork Salmon River excluding the Little Salmon and South Fork Salmon Rivers. Wild salmon and steelhead management areas were established intentionally to provide areas where wild fish would have priority management status and where there would be no direct hatchery intervention. The wild- and natural-origin fish management areas are intended to be maintained over the life of the 2019–2024 Management Plan. Many management areas overlap regions classified as wilderness or Wild and Scenic Rivers.

The Idaho Department of Fish and Game (IDFG) management plan also addresses specific river basins or portions of those basins. Relevant to the Nez Perce-Clearwater are the Palouse, Clearwater, Salmon (mouth upriver to Horse Creek), and the Little Salmon rivers. For the Palouse, the primary objective is to increase fishing opportunity. For the Clearwater, Salmon, and Little Salmon rivers, objectives include increasing fishing opportunity but are much more complex due to the presence of high-value resident fisheries and anadromous fish. Objectives include maintaining and improving fish habitat, maintaining a diversity of fishing opportunity, improving and increasing fishing access, maintaining and improving existing populations of natural and wild populations of salmon and steelhead, managing fisheries in mountain lakes to provide a diversity of fishing opportunities for anglers, maintaining long-term persistence of amphibians, and providing fishing opportunities for hatchery salmon and steelhead that satisfy different angler types.

Idaho State Wildlife Action Plan

In addition to those plans mentioned above, Idaho's State Wildlife Action Plan is a statewide plan for conserving and managing Idaho's diverse fish and wildlife and the habitats they depend on (Idaho Department of Fish and Game 2017b). It was originally written in 2005, revised in 2015, and the latest revision is from 2017. The Plan provides a checklist of wildlife species in the state; provides criteria for identifying species of greatest conservation need; and provides an assessment of each species of greatest conservation need, including their extirpation risk in Idaho. The document identifies associated conservation targets, such as habitat and species assemblage, and a narrative description for each conservation target, its viability, and prioritized threats and strategies. The plan has an emphasis on preventing additional Endangered Species Act (ESA)species listings in Idaho. There is nothing in this plan that is inconsistent with the revised forest plan.

Idaho Governor's Office of Species Conservation

The Idaho Governor's Office of Species Conservation was created in 2000 with the addition of Idaho Code 67-818 and is charged with planning, coordinating, and implementing the state's actions to preserve, protect, and restore species listed as candidate, threatened, or endangered under the ESA. It also helps to develop integrated state policies toward ESA listed species, reviews scientific information, negotiates and implements conservation plans and agreements, and recommends management plans for recently delisted species. It works in coordination with the state's natural resource agencies, while taking into consideration the economic vitality of the state. In addition, it provides constituent services for state, federal, and private stakeholders seeking assistance with ESA issues (https//species.idaho.gov). It has published a Strategic Plan that covers FY 2023-2026 that establishes a mission statement, a vision statement, and sets goals and objectives (Idaho Governor's Office of Species Conservation 2023). There is nothing in this plan that is inconsistent with the revised forest plan.

Idaho Department of Lands

Idaho Forest Practices Act

The Idaho Forest Practices Act (IFPA) was passed by the state in 1974, to assure the continuous growing and harvesting of forest tree species and to protect and maintain the forest soil, air, water resources, wildlife, and aquatic habitat. It requires that Best Management Practices (BMPs) be followed for reforestation, protection of water and soil resources, protection of wildlife habitat, proper road construction and maintenance, and protection of air quality. The Idaho Department of Lands enforces the law and monitors forest activities for compliance with state adopted BMPs. Every four years the state undertakes an audit and receives recommendations for improved standards. The U.S. Forest Service has an agreement to follow the IFPA. There is nothing in this plan that is inconsistent with the revised forest plan.

The Idaho Department of Lands Strategic Plan

The Idaho Department of Lands publishes a strategic plan at regular intervals. The latest version of the plan covers FY2023-FY2026. Its mission is to: Professionally and prudently manage Idaho's endowment assets to maximize long-term financial returns to the public schools and other trust beneficiaries and to provide professional assistance to the citizens of Idaho to use, protect, and sustain their natural resources. It includes a timber program that manages over 1 million acres, a fire program that provides cooperative fire suppression on over 6 million acres, a real estate and endowment leasing program that cover 1.4 million acres, a minerals, navigable waterways, and oil and gas program that provide statewide regulatory oversight of active and legacy extraction operations, and a program that provides forestry assistance, shared stewardship, and good neighbor authority assistance to federal, state, county, and private partners to protect and manage land throughout the state (Idaho Department of Lands 2022a). There is nothing in this plan that is inconsistent with the revised forest plan.

Idaho Forest Action Plan

The Idaho Forest Action Plan was created in 2010 and revised in 2020 and is a long-term coordinated strategy for reducing threats to Idaho's forests while increasing the social, economic, and environmental benefits they provide. The purpose is to help provide focus to landowners, agencies, collaborative groups, and partnership efforts in identifying projects and activities to reduce threats to, and increase the benefits of, Idaho's forestlands (Idaho Department of Lands 2020). It includes six goals, five of which focus on desired conditions of Idaho forests, and one is focused on a framework for implementation. These goals include: "(1) Idaho's Forests are diverse and resilient to climate changes and other natural and unique stresses, (2) The ecosystem benefits that Idaho forests provide are identified, maintained, and enhanced, (3) Forestlands with the highest benefits are identified, protected, and enhanced, (4) Forest ecosystems are resilient to human activities (development, recreation, forest practices, noxious weeds, etc., (5) Forest-based wood products are economically vibrant and sustainable, (6) Idaho has an integrated framework for implementing the Idaho Forest Action Plan, which guides project development and legislative/policy actions. This framework will promote cohesive management of Idaho's urban and rural forests." The Forest Action Plan identifies seven critical issues in Idaho, and 13 Priority Landscape Areas (PLA), and then identifies strategies, based on the goals, which address high priority issues within each PLA (Idaho Department of Lands 2015). There is nothing in this plan that is inconsistent with the revised forest plan.

Nez Perce Tribe

Nez Perce Tribe Integrated Resource Management Plan

The Nez Perce Tribe is currently in the process of developing an integrated resource management plan. This plan seeks to "establish programmatic resource management direction and balance the Tribe's economic development and resource stewardship goals within the boundaries of the Nez Perce Reservation" (Tribe 2023). The plan is in draft form at present, and the tribe is soliciting comments and holding public meetings. However, it is expected that a final version will be produced that articulates the Tribe's values and objectives with regard to natural resources on their lands. Because this plan is an ongoing planning effort subject to future revision, the following is quoted from the current version of the plan:

"This Integrated Resource Management Plan describes the Nez Perce Tribe's vision and strategy for the management of our natural and cultural resources. It has been developed to express the cultural values of the Nimiipuu; sustain and promote the welfare and opportunities of current and future generations; protect, perpetuate, and enhance the ecological diversity and long-term sustainability of our homeland;

and enhance our sovereignty. It specifically describes our overall natural and cultural resource management vision, our desired future condition of our Reservation and its resources, and our strategy to make that vision a reality for our descendants. It is the first such plan developed by and for the Nimiipuu" (Tribe 2023).

The Nez Perce Tribe Integrated Resource Management Plan is similar to the revised forest plan in that it identifies long term desired conditions; however, its scope is broader in that it describes desired conditions for not only environmental resources, but also social and cultural conditions as well. There is nothing in this plan that is inconsistent with the revised forest plan.

Nez Perce Tribe Fisheries Management Plan

Nez Perce Tribe Department of Fisheries Resource Management Plan (2013–2028): The Nez Perce Tribe's Fisheries Resource Management Plan includes a set of management goals and management objectives to achieve those goals. Management objectives include those related to achievement of escapement goals for anadromous fish, including habitat management of key populations within the Nez Perce-Clearwater such as Lolo Creek, the Potlatch River, the Upper South Fork Clearwater River, the Lochsa River, Meadow Creek, Moose Creek, and the Upper Selway River. Habitat management objectives include emphasis on watershed restoration within a "ridge-to-ridge" management philosophy where stream habitat is degraded. Fish management goals are consistent with those described in the Idaho Department of Fish and Game 5-year management plan and within the Snake River recovery and implementation plans (National Oceanic and Atmospheric Administration 2016), as the Nez Perce Tribe has worked closely with these agencies. However, the Nez Perce Tribe has set "healthy and harvestable" goals for abundance for all species of fish, and in the case of listed species, these goals far exceed federal recovery goals. The government-to-government relationship with the Forest Service, including the Nez Perce-Clearwater National Forest, is described. Co-stewardship of federal lands and cooperation on an extensive body of work occurs on the 11 National Forests with which the Nez Perce Tribe shares a working relationship. This extensive body of work includes restoration projects, fish and habitat monitoring, operation of acclimation sites, facility use, harvest access, and effects of forest management actions. There is nothing in this plan that is inconsistent with the revised forest plan.

Tribal Pacific Lamprey Restoration Plan for the Columbia River Basin

The Nez Perce Tribe is party to the Columbia River Intertribal Fish Commission's (CRITFIC) Tribal Pacific Lamprey Restoration Plan for the Columbia River Basin. The Nez Perce Tribe, along with the Confederated Tribes and Bands of the Yakama Nation (YN), and the Confederated Tribes of the Umatilla Indian Reservation (CTUIR), developed this plan with the goal of

"Immediately halting Pacific lamprey decline and ultimately restoring lamprey throughout their historic range to levels that support their unique cultural and ecological values. The Plan objectives provide an explicit and timely path to address critical uncertainties, threats and limiting factors while implementing specific restoration actions" (CRITFIC 2010).

Master Plan: Pacific Lamprey Artificial Propagation, Translocation, Restoration, and Research

The Nez Perce Tribe is party to the Columbia River Intertribal Fish Commission's Lamprey Master Plan (CRITFIC 2018). This plan includes the Confederated Tribes and Bands of the Yakama Nation (YN), the Confederated Tribes of the Umatilla Indian Reservation (CTUIR), and the Nez Perce Tribe (NPT). The plan provides a comprehensive description of lamprey propagation and translocation activities in the Columbia River basin. There is nothing in this plan that is inconsistent with the revised forest plan.

NPPC

The Northwest Power and Conservation Council (NPCC) was established in 1980 by the states of Idaho, Montana, Oregon, and Washington in accordance with the passage of the Northwest Electric Power and

Planning Act by the U.S. Congress (Northwest Power Act, [Northwest Power Act, §2 (1-6), 94 Stat. 2698.] (94 Stat. 2698, 16 USC §839). The Act authorized the Council to serve as a comprehensive planning agency for energy policy and fish and wildlife policy in the Columbia River Basin and to inform the public about energy and fish and wildlife issues and involve the public in decision-making (Northwest Power and Conservation Council 2022). This is accomplished by implementation of the Columbia River Basin Fish and Wildlife Program, which currently directs approximately 250 million dollars annually of Unite States Department of Energy-Bonneville Power Administration revenues to projects designed to protect and enhance fish and wildlife that have been affected by hydropower dams in the Columbia Basin (Northwest Power and Conservation Council 2022). Current priorities identified by the program include climate change impacts, mitigation for losses of anadromous fish, studying ocean environments, operation of Libby and Hungry Horse dams in Montana to benefit resident and anadromous fish, and studying impacts to the Columbia River Estuary (NPCC 2021). NPCC's Fish and Wildlife Program provides most of the funding for fisheries and wildlife and aquatic and terrestrial habitat work in the Pacific Northwest, including aquatic restoration work that is done on the Nez Perce-Clearwater. The NPCC Fish and Wildlife Program and the revised forest plan are complementary in the focus on restoring habitat for Endangered Species Act listed fishes. In addition, NPCC's current (2014 with 2020 amendments) fish and wildlife plan recommends "protected areas" wherein the Federal Energy Regulatory Commission (FERC) not license any new hydropower facilities in areas where hydroelectric development would have unacceptable risks of loss to fish and wildlife species of concern, their productive capacity, or their habitat. NPCC's list of protected areas covers the entire forest and most of the Pacific Northwest. There is nothing in this plan that is inconsistent with the revised forest plan.

Methodology

This analysis programmatically addresses outcomes that might result from implementing the proposed management direction in each alternative over the life of the Land Management Plan. The three watershed scales most relevant to the implementation of the Plan are sub-basin (8-digit hydrologic unit), watershed (10-digit hydrologic unit), and sub-watershed (12-digit hydrologic unit). A sub-watershed may range from 10,000 to 40,000 acres in size. For estimating the effects at the programmatic forest plan level, the assumption has been made that the types of resource management activities allowed under the alternatives are reasonably foreseeable future actions to achieve the goals and objectives. However, the specific location, design, and extent of such activities are generally not known because these activities are made at the project level based on a site-specific analysis. Therefore, discussions within this document refer to the potential for the effects to occur and are in many cases only estimates. The effects analyses are useful when comparing and evaluating alternatives but are not intended to be applied directly to specific locations on the Nez Perce-Clearwater.

Since the site specificity of future activities is not known at the programmatic forest plan level, the potential spatial and temporal effects to water quality cannot be attributed to any specific watershed, nor can quantitative estimates of potential effects to aquatic resources, such as changes in water quantity, be determined. Broad scale estimated effects and trends related to hydrologic function and watershed processes for National Forest System lands within the project area have been qualitatively estimated. Cumulative effects to water quality are described in terms of their potential to generally affect trends on the subwatershed to sub-basin scale. The temporal scale for this analysis is limited to the life of this plan, generally 15 to 20 years.

Salmon, steelhead, and bull trout stocks have been listed under the Endangered Species Act in most drainages within the interior Columbia and Snake River basins, including streams and rivers within the Nez Perce-Clearwater. While many anthropogenic and environmental factors led to the listing of these populations, habitat degradation throughout their freshwater range documented in the 1990s was a limitation to recovery efforts, (Williams et al. 1999), primarily as a result of aggressive land management activities that did not utilize Best Management Practices. Improving stream habitat and the protection of processes that maintain these habitats increases the likelihood of successful adult spawning and juvenile rearing for these listed species. Since the initiation of the PACFISH and INFISH Biological Opinion (PIBO), over 30 publications have refined understanding of what is needed to arrest stream habitat degradation and facilitate habitat improvement on federal lands. This body of literature also documents what is required by National Marine Fisheries Service (NMFS), U.S. Fish and Wildlife Service (USFWS), and Environmental Protection Agency (EPA). The PIBO included stringent monitoring requirements to determine if current land management practices were meeting PACFISH and INFISH riparian management objectives. The PIBO Effectiveness Monitoring Program compares groups of managed river reaches to groups of reference reaches at different scales to evaluate the status of stream habitat within portions of the interior Columbia River and Missouri River basins and to also document changes in habitat conditions, such as trends, since PIBO sampling began in 1999. The USFWS Range-wide Biological Opinion for Bull Trout documented improving conditions in managed watersheds in the USFWS recovery unit encompassing the Nez Perce-Clearwater National Forest (U.S. Department of the Interior 2018a). PIBO sampling (or an equivalent) will continue to occur on the Nez Perce-Clearwater.

Methods and Assumptions

(Archer and Ojala 2016) provided a detailed discussion of how the PIBO monitoring data is used to assess stream habitat conditions and trends. They discuss the challenges associated with stream assessment and the rationale behind the methods used:

"Determining the condition or status of an individual, or group of stream reaches is a difficult task because of the natural inherent variability in stream conditions due to geoclimatic and disturbance regimes (Ebersole et al. 1997). PIBO's approach is to compare the status of stream habitat conditions at sites in 'managed' watersheds (watersheds exposed to disturbance from various management actions) to habitat conditions at sites within 'reference', or relatively pristine, watersheds, which are used as a benchmark of expected condition. Because all streams are affected by natural disturbance, in assessing status we are most interested in how the range of stream habitat conditions expressed at managed sites compares to what would be expected if the stream had experienced only natural disturbance. To ascertain the status of a given site we created an index of habitat condition which accounts for some natural variability among sites and combines several stream habitat attributes (Al-Chokhachy 2010). While an index is good for determining status, it may be less sensitive when detecting trends in habitat condition over time because it averages conditions of several attributes that may be more individually responsive. Therefore, trends were estimated by measuring changes in individual stream habitat metrics, such as bank stability or large wood frequency, at a site over the duration of PIBO sampling (2001–2015)."

To evaluate the status of stream habitat conditions at a given site, PIBO develops an index score for each physical habitat attribute and constructs the index by using multiple linear regression to explain inherent differences among sites. To account for local differences in stream type and geographic location this analysis included landscape "predictor" variables, such as average precipitation, percent forested, and slope of the valley, as well as some measures of stream power (reach gradient and catchment area) as covariates in the regression models. The best multiple regression model was selected to fit each attribute using data only from the reference sub-watersheds (sample size = 217 watersheds; 10% of reference were set aside to verify model performance) to provide expected stream habitat conditions in the absence of land management activities(Al-Chokhachy 2010).

To create an overall index of physical habitat condition for a site, individual attribute scores included in the index were summed and then rescaled from 0 to 100. For complete details and a better understanding, see Al-Chokhachy et al. (2010).

To estimate trends in stream habitat condition, actual measured values (and not index scores) were used for eight stream habitat attributes. Data collected at the first sampling visit were compared with data from the last visit using the Wilcoxon rank sum test, a non-parametric statistical test that evaluates repeated measurements at the same site to determine if there has been a change in the metric value. A p-value of less than 0.10 indicates that the change is significant. Desirable changes could be either in a positive or negative direction, as, for example, increased bank stability or fewer fine sediments. The desired direction of change (positive or negative) for each habitat attribute is shown in the summary tables. The general direction of change was indicated across reference sites sampled by PACFISH and INFISH Biological Opinion (PIBO). Summary tables also show the mean value for each attribute for the first and last sampling events.

To evaluate substrate trends with data other than PIBO, substrate data collected since the Nez Perce-Clearwater's last planning period was used. Cobble embeddedness data, percent surface fines derived from Wolman pebble count data, and percent fines by depth using a McNeil core sampler were used to describe the existing condition. All of these types of data have been collected on both national forests, but the Nez Perce National Forest emphasized cobble embeddedness as a key metric, while the Clearwater National Forest emphasized percent surface fines and fines by depth. Research conducted in the mid-1980s and development of the FISHSED model (Stowell et al. 1983) in the Red River, which is in the South Fork Clearwater subbasin, informed the use of cobble embeddedness as a preferred indicator on the Nez Perce National Forest. Both concluded that as interstitial spaces are reduced by fine sediment the capacity of the stream to support juvenile anadromous salmonids is reduced (Hillman et al. 1987, Stowell et al. 1983). In other words, reduced interstitial spaces in cobble bottom streams limits the amount of habitat available for juvenile fish, particularly in the winter. Thus, winter rearing space reduced by deposited fine sediment became widely regarded as a primary factor limiting early rearing of anadromous fish.

Further, the 1995 Land Resource Management Plan Biological Opinion (National Marine Fisheries Service 1995) added two sediment Riparian Management Objectives – percent surface fines in spawning habitat and percent cobble embeddedness in rearing habitat.

Assessment of trends in percent surface fines and cobble embeddedness data, in conjunction with PIBO data, were used to assess and make conclusions about fine sediment deposited on the stream bottom to determine whether it has changed in the last planning period and whether it affected the capacity of streams supporting spawning and early rearing by juvenile salmonids.

In addition, state, tribal, and federal data, and best available scientific literature was used to provide context for fish life history and how it relates to forest management.

Measurement Indicators

PACFISH and INFISH Biological Opinion (PIBO) monitoring data: PIBO data is used in the following analysis to describe both the existing condition of stream habitat and assess the effects of the alternatives to these conditions and their trends. Metrics used to assess existing conditions include:

- Percent surface fines at pool tailouts
- Median grain size of the substrate (D50)
- Percent pools
- Residual pool depth
- Streambank angle

- Percent undercut banks
- Large wood in the stream channel
- Streambank stability
- Aquatic macroinvertebrate diversity

The protocol for collection for collection and analyses of this data is fully described in Archer et al. (2012), Kershner (2004) and Kershner(2004), and Archer and Ojala (2016).

For the most recent report, the analysis of stream habitat data included comparisons of data from referenced and managed sites using a habitat index approach to determine if differences were statistically significant according to methods described in Al-Chokhachy et al. (2010). A predictive relationship was developed between landscape and environmental characteristics and habitat conditions at reference sites to minimize sources of variation. This statistical approach controls for inherent differences in climate and landscape characteristics among sites (Meredith et al. 2012, Archer and Ojala 2016). For analysis of macroinvertebrate data, distribution of observed versus expected macroinvertebrate scores in reference and managed sites was analyzed according to methods described in Hawkins (Hawkins 2006).

Reference conditions from PIBO sites across the Interior Columbia River Basin provide a representation of the natural range of variability in aquatic ecosystems in the Interior Columbia River (Kershner, Archer, et al. 2004), including the Nez Perce-Clearwater. Given the wide range of values seen in data from reference sites and inherent natural disturbance regimes that shape stream habitats, a range of indexed reference conditions is more useful than comparisons of single values that represent only one end of the distribution of values seen in reference reaches (Kershner and Roper 2010, Al-Chokhachy et al. 2010). The range of conditions exhibited in PIBO data collected from reference sites can be interpreted as the range of natural variability for streams; if the range of conditions from managed sites is different than the range for reference sites, management actions may have had an effect (Archer and Ojala 2016).

PIBO data summaries are included for each subbasin with enough sites to conduct a statistical analysis.

The Land Management Plan would maintain the use of PACFISH and INFISH Biological Opinion (PIBO) monitoring data or a future equivalent collected at a subset of sites on the national forest at regular intervals to evaluate trends towards desired conditions. While the Land Management Plan does not contain numerical riparian management objectives like PACFISH/INFISH did, descriptive desired conditions contained in the Land Management Plan would be used to guide project location, development, and actions. Because of the lag time between projects and effects, as well as the tremendous variability that can result from localized weather events, PIBO data analyzed at the Nez Perce-Clearwater scale is actually a more rigorous method to ascertain whether or not plan components designed to protect and restore the aquatic environment are effective. All this information would enable the national forest to adapt its management strategies and adjust project decisions in the future, if needed, based upon what has been learned.

One potential management approach to show achievement of desired conditions of the Land Management Plan would be a multiscale analysis, as described in Appendix 4. Multiscale analysis, a refinement of watershed analysis, has been a widely applied methodology that was first required for use by the Forest Service in the Northwest Region (Henjum et al. 1994). It was also described and recommended for use in the Interior Columbia Basin key and priority watersheds by PACFISH and INFISH strategies (U.S. Department of Agriculture 1995c) and is recommended for inclusion in plan revisions by the Interior Columbia Basin Ecosystem Management Project (2014a) strategy. The multiscale analysis strategy described in Appendix 4 has been clarified to aid with integration and implementation.

Substrate Data Other Than PIBO: Because of the predominance of the highly erosive Idaho Batholith geology on both the Nez Perce and Clearwater National Forests, deposited sediment in streams was recognized as a key limiting factor for anadromous salmonids during the previous forest planning efforts. Direction in both previous plans related to aquatic resources was based on contemporary research at the time identifying deposited sediment as a primary limiting factor for salmonids spawning and rearing in streams on the Nez Perce-Clearwater and a primary risk to beneficial uses as defined under the Clean Water Act. Deposited sediment in north central Idaho streams within the Idaho Batholith geologic type was a primary focus in both forest plans. Literature supporting this conclusion included Bjornn (1971), Bjornn et al. (1977), and Stowell et al. (1983), among others. In the years following PACFISH and INFISH implementation, as well as the implementation of the Northwest Forest Plan (U.S. Department of Agriculture 1994), many of the activities that were causing problems at the time of these publications were stopped, effectively arresting a great deal of the degradation occurring from streamside road building and harvest. In addition, the Roadless Rule and the Idaho Roadless Rule also limit construction of new roads.

The primary effects to aquatic ecosystems to be analyzed would result from the implementation of the Land Management Plan action and preferred alternatives, as compared to the No Action Alternative. Comparison is made between alternatives based on their relative ability to move the resources toward desired conditions.

Summary of Effects to Aquatic Threatened or Endangered Species, Species of Conservation Concern, and Species of Public Interest: The existing condition and indirect, and cumulative effects of the alternatives for the following aquatic species are summarized using the PIBO metrics described, as well as other sources of effects:

- Snake River spring and summer Chinook salmon (Oncorhynchus tshawytscha) – threatened, Salmon River Basin
- Snake River fall Chinook salmon (Oncorhynchus tshawytscha) – threatened, Clearwater and Salmon River Basins
- Snake River sockeye salmon (Oncorhynchus nerka) – endangered, Salmon Basin
- Snake River steelhead (Oncorhynchus mykiss) – threatened, Clearwater and Salmon Basins
- Columbia River bull trout (Salvelinus confluentus) – threatened, Clearwater and Salmon Basins
- Pacific lamprey (Entosphenus tridentatus) – Species of Conservation Concern, Salmon and Clearwater Basins
- Spring and summer Chinook salmon (Oncorhynchus tshawytscha) – Species of Public Interest, Clearwater Basin-
- Coho Salmon (Oncorhynchus kisutch) – Species of Public Interest, Clearwater River Basin

Affected Environment

Introduction

The current condition of riparian and stream habitats varies widely across the planning area, ranging from largely unaffected by human disturbances in designated wilderness areas to highly disturbed with varying degrees of impaired function.

The Nez Perce-Clearwater includes portions of 11 subbasins (HUC8), including Palouse, Lower North Fork Clearwater, Upper North Fork Clearwater, Clearwater, Middle Fork Clearwater, South Fork Clearwater, Lochsa, Upper Selway, Lower Selway, Lower Salmon, Little Salmon, and Middle Salmon–Chamberlain. Within the context of the Interior Columbia River Basin, subbasins within the Nez Perce-Clearwater support a significant percentage of remaining spawning and rearing habitats accessible to anadromous fish in the Snake River basin. A substantial number of the drainages on the Nez Perce-Clearwater were identified as supporting strongholds for at-risk fish species (Lee et al. 1997), which include bull trout and westslope cutthroat trout. Other assessments indicate watersheds on the Nez Perce-Clearwater with high potential to support strongholds for at-risk anadromous fish species, including spring and summer Chinook salmon and steelhead trout (U.S. Department of Agriculture 1998b, 2001b, 2003e).

The most notable alteration of upland and riparian conditions that has influenced stream process and function across the Nez Perce-Clearwater is road development (U.S. Department of Agriculture 1998b, 2001b, 2003c, Ecovista 2003, U.S. Department of Agriculture 2003e, 1999). Road development has been correlated to instream conditions including substrate composition, large woody debris, and number and quality of pools on both the Clearwater and Nez Perce National Forests (Huntington 1995, Meredith et al. 2012, U.S. Department of Agriculture 2003c).

High levels of deposited sediment and simplified habitat conditions are correlated with roaded development in watersheds, particularly in riparian areas. System roads cover an estimated 2,400 acres, or 600 road miles, within riparian management zones on the Nez Perce National Forest and an estimated 4,000 acres, or 1,000 road miles, within riparian management zones on the Clearwater National Forest. As long as road prisms persist on the landscape, there is little to no chance for recovery of complete floodplain function or condition. Routine maintenance, hydrologically disconnecting roads, stormproofing roads, and site-specific improvements, however, can be made to mitigate effects.

The specific effects of historical road development practices on watershed condition and their correlation to instream habitat, particularly deposited sediment, are well described in the literature. As described in Furniss et al. (1991), construction of roads and road networks can lead to greatly accelerated erosion rates in watersheds and increased sedimentation in streams following road construction can be dramatic and long lasting (Swanson and Dyrness 1975, Beschta 1978, Reid and Dunne 1984, Haupt 1959). These conditions were more broadly addressed in the Interior Columbia Basin Ecosystem Management Plan (Quigley and Arbelbide 1997c, b). Surface erosion from road surfaces, cut banks, and ditches represents a significant source, and in some landscapes the dominant source, of road-related fine sediment input to streams (Gucinski et al. 2001). Increased sediment delivery to streams after road building has been well documented in the research literature for the Pacific Northwest and Idaho (Bilby et al. 1989, Megahan and Kidd 1972, Reid and Dunne 1984). The negative effects of roads on physical instream habitat and aquatic biota have been summarized in a comprehensive review by Trombulak and Frissell (2000). However, many of the deleterious effects associated with historical road development specifically relate to practices that are no longer implemented (harvest next to streams, road crossings that restrict channels, roads built on least cost principles, etc.). Currently employed U.S. Forest Service Best Management Practices (U.S. Department of Agriculture 1994) have been shown to be largely effective at mitigating for negative effects of roads.

Other alterations of riparian and stream conditions include historic dredge mining and domestic livestock grazing. These activities are not as widespread as road development but in many cases have resulted in significant alterations of both the stream and riparian environment. Some riparian areas most altered by historic dredge mining are located within or adjacent to spawning and rearing habitat for anadromous fish with very high potential for high productivity of juvenile fish, most notably tributaries to the Upper South Fork Clearwater River, the mainstem South Fork Clearwater River, and reaches of Lolo Creek.

A substantial percentage of the Nez Perce-Clearwater's land base is contained within designated wilderness or is classified as roadless under the Idaho Roadless Rule. In these areas, it is assumed natural processes drive riparian and stream conditions. Exceptions could include watersheds that are developed in their headwaters, or those that contain non-native species.

Riparian Areas

In general terms, riparian areas are lands at the interface between land and a river or stream and wetlands are defined by the Environmental Protection Agency as "lands that are saturated with water all year or for varying periods of time during the year, including during the growing season." Both encompass unique and diverse vegetation types that are closely associated with lakes, streams, ponds, marshes, swamps, bogs, fens, and other areas of high or fluctuating water tables. Although they may occupy a small percentage of the landscape, riparian areas provide important habitat for many terrestrial and aquatic species, including connectivity of habitat from headwaters to downstream areas.

The composition of the vegetation and the structure and pattern of the riparian areas and wetlands across the Nez Perce-Clearwater are highly diverse. Plant communities may be dominated by shrubs with few trees, particularly in the Lower Salmon and Lower Little Salmon subbasins, or they may be forested. Forested riparian areas may be comprised of Western redcedar, grand fir, Douglas-fir, Western larch, and Western white pine on the warmer sites, and lodgepole pine, spruce, and subalpine fir on colder sites. Shrubs include alder, willow, red-osier dogwood, elderberry, buckthorn, thimbleberry, twinberry, and hawthorn. Forbs and grass-like plants that occupy these sites are quite diverse. The vegetative structure may include many decayed and dead trees and multiple layers of vegetation that include submerged vegetation along open water margins, as well as plants that grow in conditions with variable amounts of soil saturation. The pattern of riparian and wetland ecosystems varies from relatively narrow strips of land along perennial and intermittent streams in deeply incised, steep mountain valleys to adjacent wetlands to the wider valleys of the North Fork Clearwater River, Selway River, Lochsa River, and South Fork Clearwater Rivers, as well as the lower reaches of some major tributaries. They may be interconnected in a linear fashion down hillsides and in valleys, they may occur in clusters, or they may occur as isolated microsites in other ecosystems.

Riparian ecosystems are equally important habitat to wildlife for feeding, drinking, cover, breeding season habitats, and habitat connectivity. Many wildlife species are associated with riparian ecological systems, including neotropical migrant birds, native upland birds such as mountain quail and ruffed grouse, beaver, Canada lynx, and fisher. Rare and native plants are also associated with riparian areas.

Riparian Management Zones

Areas currently known and referred to as Riparian Habitat Conservation Areas will be called Riparian Management Zones under the Land Management Plan.

As previously discussed, PACFISH amended both the Nez Perce and Clearwater Forest Plans in 1995 (U.S. Department of Agriculture and U.S. Department of the Interior 1995a). INFISH also amended the Clearwater Forest Plan in 1995 (U.S. Department of Agriculture 1995c) applicable only to watersheds where anadromous fish are blocked but was extirpated on the Upper and Lower North Fork Clearwater subbasins above Dworshak Dam or historically absent in the Palouse River subbasin. The background behind these documents has been previously discussed in the Relevant Laws, Regulations, and Policy section and the Methodology section.

PACFISH and INFISH were designed to provide interim aquatic and riparian management guidance that would protect habitat for anadromous salmonids and bull trout, halt further degradation, and begin recovery. While these strategies were initially intended to be replaced in 18 to 36 months, they have now been in place on the Nez Perce-Clearwater for over 25 years. They established and defined interim Riparian Habitat Conservation Areas (RHCAs), prescribed specific standards and guidelines that limited activities within the Riparian Habitat Conservation Areas, and established Riparian Management Objectives (RMO). RMOs assigned numeric objectives for the following metrics: stream temperature, pieces of large wood per mile, number of pools per mile, lower bank angle, width to depth ratio, and percent undercut streambanks.

RHCAs identified four categories of stream or water bodies with the following standard widths:

Category 1: Fish-bearing streams. Interim Riparian Habitat Conservation Areas consist of the stream and the area on either side of the stream extending from the edges of the active stream channel to the top of the inner gorge, or to the outer edges of the 100-year floodplain, or to the outer edges of riparian vegetation, or to a distance equal to the height of two site-potential trees, or 300 feet slope distance (600 feet, including both sides of the stream channel), whichever is greatest.

Category 2: Permanently flowing non-fish-bearing streams. Interim Riparian Habitat Conservation Areas consist of the stream and the area on either side of the stream extending from the edges of the active stream channel to the top of the inner gorge, or to the outer edges of the 100-year floodplain, or to the outer edges of riparian vegetation, or to a distance equal to the height of one site-potential tree, or 150 feet slope distance (300 feet, including both sides of the stream channel), whichever is greatest.

Category 3: Ponds, lakes, reservoirs, and wetlands greater than 1 acre. Interim Riparian Habitat Conservation Areas consist of the body of water or wetland and the area to the outer edges of the riparian vegetation, or to the extent of the seasonally-saturated soil, or to the extent of moderately and highly unstable areas, or to a distance equal to the height of one site-potential tree, or 150 feet slope distance from the edge of the maximum pool elevation of constructed ponds and reservoirs or from the edge of the wetland, pond or lake, whichever is greatest.

Category 4: Seasonally flowing or intermittent streams, wetlands less than 1 acre, landslides, and landslide-prone areas. This category includes features with high variability in size and site-specific characteristics. At a minimum the interim Riparian Habitat Conservation Areas must include:

- the extent of landslides and landslide-prone areas;
- the intermittent stream channel and the area to the top of the inner gorge;
- the intermittent stream channel or wetland and the area to the outer edges of the riparian vegetation;
- for Key (priority) Watersheds, the area from the edges of the stream channel, wetland, landslide, or landslide-prone area to a distance equal to the height of one site-potential tree, or 100 feet slope distance, whichever is greatest;
- for watersheds not identified as Key Watersheds, the area from the edges of the stream channel, wetland, landslide, or landslide-prone area to a distance equal to the height of one-half site potential tree, or 50 feet slope distance, whichever is greatest.

Current Condition of Riparian Management Zones

Riparian management zones on the Nez Perce-Clearwater have been affected by road construction. They have also been affected by past timber harvest, although only limited vegetation treatments have occurred in riparian management zones since PACFISH and INFISH amended the plans in 1995. Table 121 summarizes these activities at the subbasin scale and includes the number of road and stream crossings, as well as miles of roads within riparian management zones.

Table 121. Riparian management zones (RMZ) conditions related to roads and past timber harvest.

Subbasin	Acres in Nez Perce-Clearwater Area	Miles of Roads in RMZs	% RMZs with Past Timber Harvest	# of Road and Stream Crossings
Palouse/Hangman	55,547	67	5	344
Lower North Fork Clearwater	89,147	62	3	173
Upper North Fork Clearwater	776,015	320	2.4	877
Clearwater	139,553	181	16	586
Lochsa	722,316	155	1	363
Middle Fork Clearwater	67,563	25	2	103
Upper and Lower Selway	835,572	35	<1	132
South Fork Clearwater	516,497	288	1	1,017
Lower Salmon/Little Salmon	234,975	98	1	395
Middle Salmon-Chamberlain	422,658	42	<1	172

Data Source: Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a)

Riparian vegetation and condition have also been affected by domestic livestock grazing. Riparian areas most susceptible to the effects of grazing are generally low gradient with low confinement and drier climate, although higher confined streamside areas may be affected by trailing. Active grazing allotments are currently present in many areas of the Nez Perce-Clearwater, with the Lower Salmon and Lower Little Salmon supporting the most acres. Cattle and horses are the only livestock currently grazed. Fewer acres of the national forest lands are presently actively grazed than were grazed during the last planning cycle.

Substantial lengths of riparian areas on the Nez Perce-Clearwater were dredge mined in the early- to mid-1900s, particularly in tributaries in the South Fork Clearwater subbasin and the mainstem river itself. Watersheds exhibiting the most profound changes include Red River, Crooked River, Newsome, Leggett, and Cougar creeks.

Effects from past dredge mining activity are also present in specific areas in the following locations:

- Lower Salmon – Upper Little Slate Creek
- Middle Salmon-Chamberlain – Upper Crooked Creek and Meadow Creek
- Clearwater – Middle Lolo Creek, Orofino Creek
- Upper North Fork Clearwater –Vanderbilt/Bostonian, Moose Creek, Orogrande/French creeks
- Palouse River

Riparian areas across the Nez Perce-Clearwater have also been affected by natural disturbances, most notably floods, landslides, and wildfire. Floods, landslides, and debris torrents are natural events, often associated with wildfires, which are included in the disturbance regimes of many stream reaches on the Nez Perce-Clearwater. Although the short term effects may be deleterious, particularly in streams already degraded, streams on the national forest are dependent on these fire and disturbance events to sort gravels, create spawning habitat for salmonids, and recruit large amounts of woody debris in a pulse event, all of which can increase habitat complexity and productivity long-term (Reeves et al. 1995, Beechie and Bolton 1999).

Fire

One of the most widespread events that affected streams in many watersheds across the Nez Perce-Clearwater occurred in the winter of 1995 to 1997. It included a series of rain-on-snow and high precipitation events. Areas within the Selway, Lochsa, Lower Clearwater, and the notably low elevation portions of the North Fork Clearwater basins were most affected, resulting in a series of mass failure events in both natural landscapes and those with roads and timber harvest units.

Fire regimes in riparian areas are generally different from upland regimes. Fire in riparian areas tends to be less frequent and of lower intensity than surrounding uplands (Pettit and Naiman 2007, Dwire and Kauffman 2003), but longer fire intervals may result in higher accumulation of fuels, fuels, resulting in high fire severity if the riparian area burns under extreme conditions (Russell and Jones 2001, Everett et al. 2003). Agee (1998) observed a riparian zone in a high elevation tributary to the Salmon River that burned at higher severity than surrounding uplands on the Payette National Forest and surmised that fuels in riparian zones had accumulated at a higher rate due to less frequent fire, when compared to the uplands that burned at lower severity. However, others have observed that fire severity in riparian areas is dependent on upland severity (Halofsky and Hibbs 2008, Arkle and Pilliod 2010) or other factors unrelated to fuel type and distribution, such as landform features (Everett et al. 2003, Moore and Richardson 2012). Halofsky and Hibbs (2008) concluded that high fire severity in riparian areas in southwest and central Oregon was strongly associated with high fire severity in the adjacent uplands and steep slope gradients.

Within the Nez Perce-Clearwater, a substantial amount of acreage has been burned by wildfires since the last planning effort, particularly in tributaries to the Salmon River and particularly in the summer of 2007. That summer a combined acreage greater than 250,000 acres burned over a period of three months starting in mid-July. Substantial acreage burned in 2001 and 2005 in the Lochsa, Selway, South Fork Clearwater, Lower Salmon, and Middle Salmon-Chamberlain subbasins. In 2012, late season ignitions resulted in over 80,000 acres burned in tributaries to the Salmon, Middle Salmon-Chamberlain, South Fork Clearwater, and Lochsa subbasins during the month of September. In 2015, substantial acreage burned in most subbasins on the Nez Perce-Clearwater. Combined burned acreage for 2007 and 2015 approached 500,000 acres.

To assess how wildfires have affected riparian areas on the Nez Perce-Clearwater under more extreme fire conditions, a subset of the largest fires was selected from the 2007, 2012, 2013, 2014, and 2015 fire seasons. Fire severity within streamside riparian management zones was estimated using Burned Area Reflective Classification (BARC) satellite imagery mapping, subsequently refined by field observations. Acres of high, moderate, and low severity and unburned within riparian management zones were summarized for each fire to provide a gross estimate of the percentage within each category. The results of this analysis are displayed in Figure 35 and Figure 36.

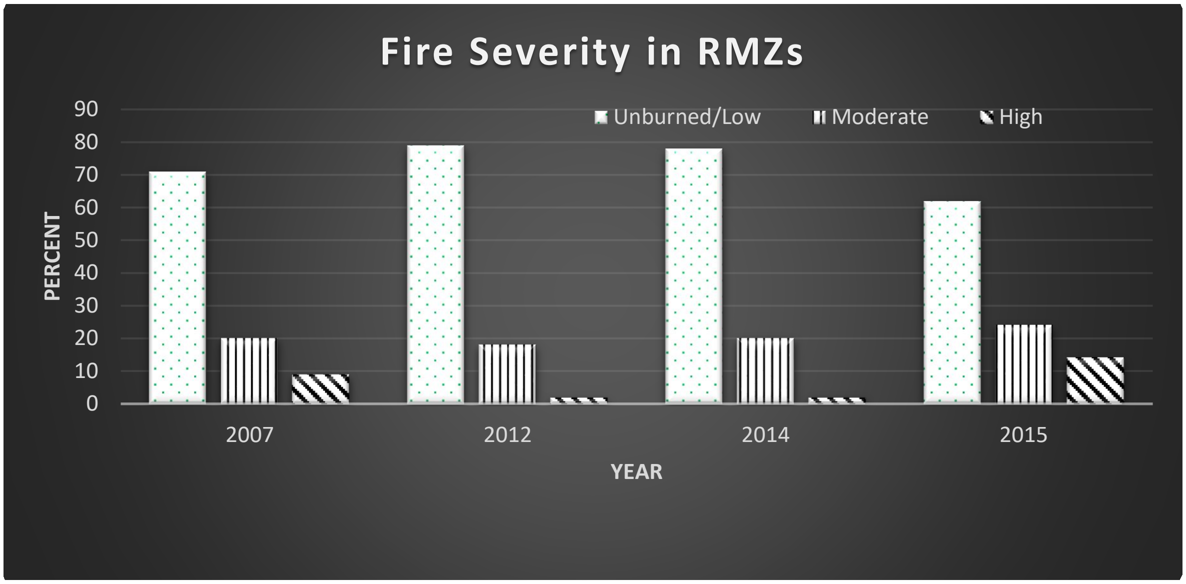

Figure 35. Riparian Management Zones fire severity in 2007, 2012, 2014 and 2015. All fires combined.

Data Source: Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a)

As Figure 35 illustrates the percent of high severity fire in riparian management zones has been low for the years included in the above analysis relative to the percent of unburned and low severity. These percentages can be compared to severity in uplands, or non-riparian management zones, as displayed in Figure 36, below. These indicate that upland areas in general have had a higher percentage of total fire acres that burn at high severity than riparian management zones from 2007 to 2015. This data suggests streamside riparian areas on the Nez Perce-Clearwater maintain an inherent resistance to high fire severity. Recent large wildfires have followed a consistent pattern of low to moderate fire severity with pockets of high severity in streamside riparian areas, with substantial portions remaining unburned. Unpublished Burned Area Reflective Classification maps from 2007 through 2015 indicate high severity fire in riparian areas was nearly always associated with high severity in adjacent uplands, which is consistent with the findings of Halofsky and Hibbs (2008). An exception was noted with the 2007 Poe Cabin Fire, where some riparian corridors along tributary streams to the Snake River burned at high and moderate severity, while surrounding uplands burned at low severity. In this case, surrounding uplands were grasslands, and riparian areas were comprised of brush and small hardwoods. Riparian corridors burning at higher severity than surrounding uplands were not evident in forested habitat types within this fire perimeter.

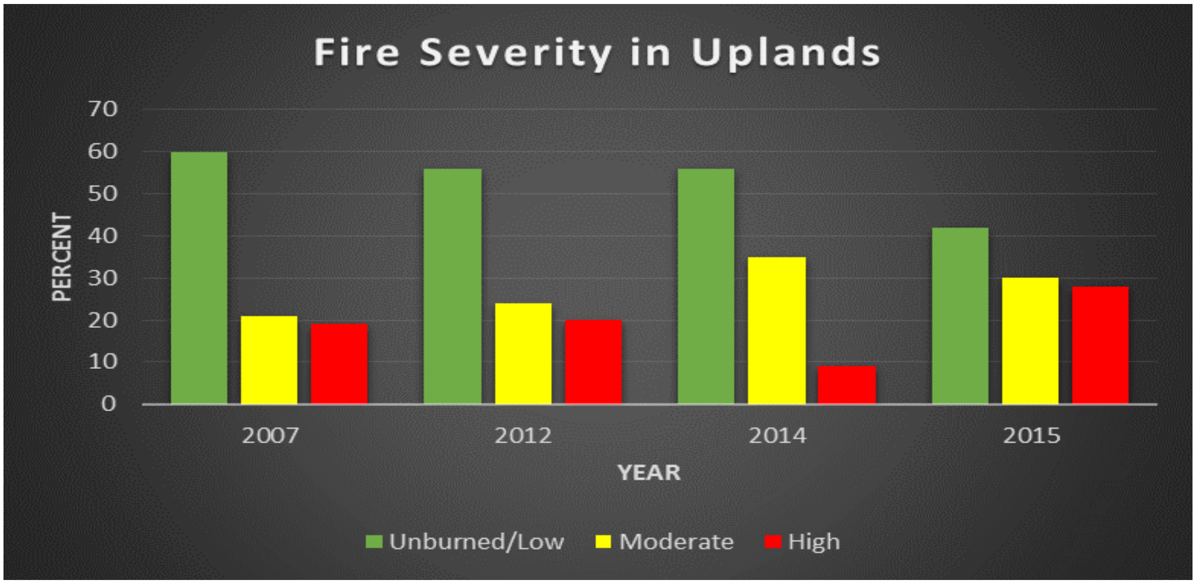

Figure 36. Upland fire severity in 2007, 2012, 2014 and 2015. All fires combined.

Data Source: Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a)

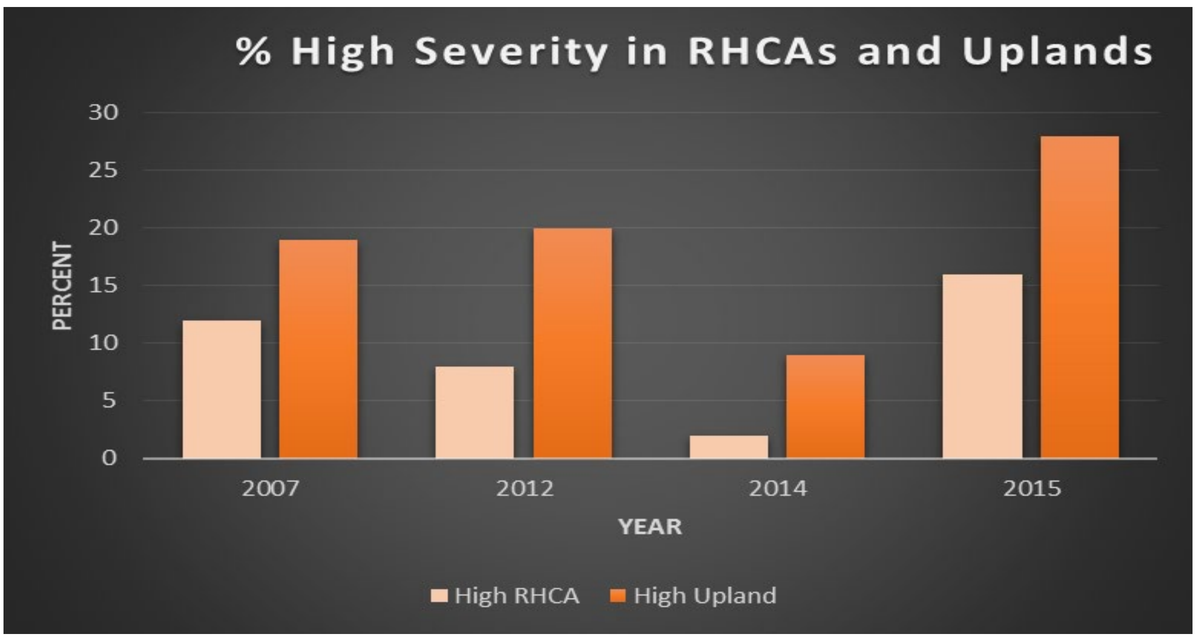

Figure 37. Comparison of high severity fire in uplands and riparian management areas.

Data Source: Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a)

Although the relative percentage of riparian acres burned at high severity has been consistently low within large fire perimeters, percent of high fire severity within individual HUC12 watersheds has been much more variable. In some cases, high severity fire in riparian management zones has resulted in short term adverse effects to fish and habitat. For example, the McGuire Fire caused direct mortality of fish, presumably from high water temperatures adjacent to very high severity fire as it burned through the adjacent riparian area. In the Sheep Fire, a series of intense, summer thunderstorms within the John Day

Creek drainage generated slope failures and debris torrents initiated in upland areas that burned at high severity. Some of these slope failures were associated with roads. In both cases, high severity fire in riparian areas was included within large blocks of high severity fire on the uplands. Therefore, even though the percent of high severity within riparian management zones is low at a broad scale, at finer scales it can be much higher and result in significant effects to riparian resources. Short-term deleterious effects are often followed in subsequent decades by beneficial effects, as habitat improves following fires. The species that occupy the Nez Perce-Clearwater have evolved within this landscape that is driven and shaped by fire.

Streams

The Nez Perce-Clearwater supports a wide range of stream types and highly variable stream habitats, depending on factors such as gradient, aspect, watershed size, geology, substrate, and upland and streamside disturbances. Streams can be highly dynamic. While the rates of change differ among streams, the concept of change applies across the landscape.

Current stream process and function are similar to historic processes in many streams but differ in others. Human activities have altered stream channels by direct modification such as channelization; removal of large woody debris; dams and diversions; historical log drives; and the building of infrastructure such as roads, railways, bridges, and culverts that have encroached on riparian areas and stream channels. Humans have also indirectly affected the incidence, frequency, and magnitude of disturbance events. This has affected the inputs and outputs of sediment, water, and vegetation. These factors have combined to cause changes in channel conditions throughout many parts of the Nez Perce-Clearwater, resulting in aquatic and riparian habitat conditions different from those that existed prior to human development. Natural disturbances, primarily wildfire, floods, and landslides, combined with human-caused disturbances, such as timber harvest, fire suppression, road construction, mining, dams, introducing non-native species, recreation, grazing, and altered food web, over the last century have led to changes in the physical watersheds and in the fish and amphibians dependent on them (Lee et al. 1997, Naiman et al. 2012, Naiman 2013, Poff et al. 2011, Rieman et al. 2015).

PACFISH and INFISH Biological Opinion (PIBO) Data Status Forestwide – Existing Condition

PACFISH and INFISH Biological Opinion (PIBO) data has been summarized for each subbasin on the Nez Perce National Forest where enough data was available to complete a statistically robust analysis. The following discussion of existing stream conditions is focused on a broader scale and includes data from all sites across the Nez Perce-Clearwater, as summarized in Table 122.

Table 122. Summary of Index Scores across the Nez Perce-Clearwater National Forest Stream conditions across the plan area.

Metric	Data/Site Type	Index Score	P-value	Significant Difference Between Managed and Reference?
Overall – All metrics combined	Managed	43.29	<0.01	Yes
Overall – All metrics combined	Reference EcoRegion	51.67	<0.01	Yes
Residual Pool Depth	Managed	4.32	<0.01	Yes
Residual Pool Depth	Reference EcoRegion	5.48	<0.01	Yes
Pool Percent	Managed	4.45	0.09	Yes

Metric	Data/Site Type	Index Score	P-value	Significant Difference Between Managed and Reference?
Pool Percent	Reference EcoRegion	5.01	0.09	Yes
Median Substrate (D50)	Managed	5.46	0.99	No
Median Substrate (D50)	Reference EcoRegion	5.47	0.99	No
Pool Fines	Managed	4.74	0.09	Yes
Pool Fines	Reference EcoRegion	5.45	0.09	Yes
Large Wood Frequency	Managed	5.71	<0.01	Yes
Large Wood Frequency	Reference EcoRegion	6.67	<0.01	Yes
Bank Angle	Managed	5.43	0.73	No
Bank Angle	Reference EcoRegion	5.3	0.73	No
Macroinvertebrate Assemblage	Managed	0.92	0.24	No
Macroinvertebrate Assemblage	Reference EcoRegion	0.95	0.24	No

Data Source:(Saunders et al. 2020) (PacFish/InFish Biological Opinion Monitoring Program) (statistical significance at p<0.10)

The data presented above indicates that overall stream conditions in 64 managed watersheds on the Nez Perce-Clearwater, when considered collectively, are outside the range of natural variability and in a less than desired condition. The data suggests that residual pool depth, pool percent, and large wood frequency are degraded and less favorable for salmonids when compared against reference subwatersheds. In addition, pool median substrate size, bank angle, and macroinvertebrate assemblage in managed subwatersheds are not statistically different than reference and that pool fines exhibit more favorable conditions than in reference watersheds. It should be noted that the term "reference" should not be confused with "undisturbed."

Additional discussion of data up to 2016 can be found in the Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a).

PACFISH and INFISH Biological Opinion (PIBO) Data Trends – Forestwide

As previously described, the PACFISH and INFISH Biological Opinion (PIBO) broad-scale monitoring program was initiated by the Forest Service and Bureau of Land Management in the late 1990s to assess the effectiveness of the PACFISH and INFISH amendments, as required by programmatic Endangered Species Act consultations for salmon, steelhead, and bull trout in the Interior Columbia River Basin. As in the preceding section, the following information is summarized from (Saunders et al. 2020)

Trends in stream conditions were assessed at managed sites on the Nez Perce-Clearwater using the same metrics used to assess existing conditions, with the addition of two metrics: percent undercut streambanks and streambank stability. However, unlike comparisons to reference conditions using index scores, raw data was used to assess trends comparing data collected at Year 1 to data collected in the last year the site was measured. A Wilcoxon Rank Sum Test, a non-parametric comparison of means, was used to determine statistical significance. Results are summarized in Table 123.

Table 123. Stream habitat attribute trends using actual values on all managed sites on the Nez Perce-Clearwater

Metric	Time Value First Year	Time Value Last Year	Sample Size (n)	% Change	P-value	Statistically significant improvement (P<0.10)	Desired vs. Actual Change
Overall Index*	40.52	42.47	65	4.8	0.228	No	+/NS
Residual Pool Depth	0.35	0.34	67	-2.9	0.428	No	+/NS
Pool Percent	47.44	47.15	67	-0.6	0.846	No	+/NS
Median Substrate (D50)	0.0398	0.0458	66	134.9	.04	Yes	+/+
Pool Fines	32.37	33.48	66	-1.23.4	0.68	No	-/NS
Large Wood Frequency	279.34	318.07	67	13.9	0.038	Yes	+/+
Bank Angle	100.61	103.54	67	2.9	0.112	No	-/NS
Macroinvertebrate Observed/ Expected	0.87	0.91	66	4.6	0.033	Yes	+/+
% undercut banks	38.65	41.1	67	6.3	0.302	No	+/NS
Bank Stability	84.21	85.33	67	1.3	0..478	No	+/NS

Data Source: (Saunders et al. 2020) Based on PIBO Monitoring 2001-2019.

* Overall Index is forestwide and is calculated independently of individual indices.

The above table shows overall trends in stream conditions at managed sites between the first year PIBO data was collected and the last. The specific metrics that indicated a statistically significant improvement include large wood frequency, median substrate (D50), and macroinvertebrate assemblage.

Trends in stream habitat attributes across the Nez Perce-Clearwater are shown in Table 123. There were three attributes, including Observed and Expected macroinvertebrate score, large wood frequency, and median substrate size that have improved since the implementation of PACFISH and INFISH Biological Opinion (PIBO), and all other metrics have not significantly changed at the national forest scale. Although the majority of metrics have not changed at this scale, none of the metrics have significantly degraded from 2001 to 2019. While some metrics remain below ecoregion reference benchmarks, the current Forest Plan as amended arrested further degradation, and in many cases allowed habitat conditions in streams to improve through passive restoration while allowing for forest management activities. In a 2018 Biological Opinion related to the effects of 26 forest plans on bull trout, including the current Plans for the Nez Perce-Clearwater National Forests, as amended, the U.S. Fish and Wildlife Service agreed that based on the results of the Aquatic and Riparian Effectiveness Monitoring Program (AREMP) and PIBO monitoring programs, changes in grazing activities have resulted in improvements to stream habitat conditions previously impaired by grazing, and that those improvements were likely to continue, as current plans as amended have allowed for passive recovery of instream conditions (U.S. Department of the Interior 2018a, 74, 78).

PACFISH and INFISH Biological Opinion (PIBO) Data Status at the Sub-basin Scale

To further identify areas that need improvement, PACFISH and INFISH Biological Opinion (PIBO) analyzes data at finer scales. PIBO data was summarized by subbasin when sample sizes were sufficient for statistical inference. The Nez Perce-Clearwater includes portions of 11 subbasins (HUC8), including Palouse/Hangman, Lower North Fork Clearwater, Upper North Fork Clearwater, Lower Clearwater, Middle Fork Clearwater, South Fork Clearwater, Lochsa, Upper Selway, Lower Selway, Lower Salmon, Little Salmon, and Middle Salmon-Chamberlain. Of the 11 subbasins, five have enough sites to monitor for status at this scale, including the Lower Clearwater, Lower Salmon, Upper North Fork Clearwater, Lochsa, and South Fork Clearwater. One additional site (Lower Selway) does not have enough sites for status but does have enough to monitor trends. Because the Palouse subbasin is not used by Endangered Species Act listed species and does not provide critical habitat, it is not discussed further in this document.

Clearwater Subbasin

Land ownership in this subbasin is highly mixed and comprised of private, state, federal, and tribal holdings. Potlatch Corporation and the Idaho Department of Lands manage (U.S. Department of the Interior 2018a) substantial portions of the land base, and properties managed by these two entities are highly intermixed with those administered by the national forest. On the Nez Perce-Clearwater, the three largest tributaries in the Clearwater River subbasin include the Potlatch River, Orofino Creek, and Lolo Creek.

Only 46 percent of the subbasin is managed by the Forest Service. Road density is high, averaging over four miles per miles squared (mi/mi^2). Of the 11 subbasins in the proposed action area, the Clearwater River is possibly the most departed from reference conditions. The mainstem Clearwater River provides spawning and rearing habitat for Snake River fall Chinook salmon. It serves as a migration corridor for steelhead trout and spring and summer Chinook salmon and provides overwintering habitat for both adult and juvenile salmon and steelhead. Westslope cutthroat trout, bull trout, and redband trout are present in the river as water temperatures allow. Cold water releases from Dworshak Reservoir in the mid-to-late summer may facilitate use of this section of river by these species while providing thermal refuge for returning adult fall Chinook salmon and steelhead trout in August and September.

PIBO data has been collected from 10 managed sites in the Clearwater subbasin and were last summarized in 2020 (Saunders et al.).When habitat indicators are combined to calculate the overall index value, managed sites scored lower than ecoregion reference sites (Figure 38). Of the seven indicators used, four were not significantly different from reference sites, and three — pool fines, median substrate size (D50), and macroinvertebrate Observed/Expected (OE score) — scored lower than reference sites (Table 124). All but one indicator had no significant trend, positive or negative. One indicator, streambank stability, showed a trend away from reference or desirable conditions (Table 125).

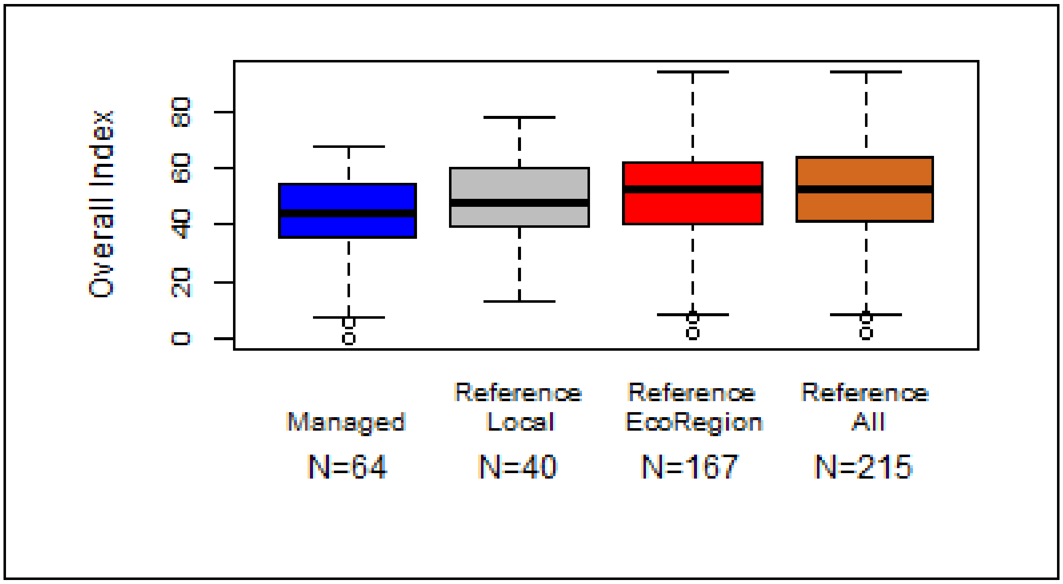

Figure 38. Overall index values in the Clearwater subbasin (Saunders et al. 2020). Median and range of index values for managed sites, reference sites within the ecoregion, and reference sites for the entire PACFISH and INFISH Biological Opinion (PIBO) study area.

Lower Salmon Subbasin

The Lower Salmon and Lower Little Salmon subbasins are intermixed with private, Bureau of Land Management, and State of Idaho lands. The national forests manage 57 percent of the subbasins' acreage. The Lower Salmon has enough managed sites for status and trends, while the Little Salmon does not.

Specific reaches in many watersheds have been affected by past and ongoing livestock grazing and mining activities. Mining has resulted in substantial effects to riparian conditions in Upper Little Slate Creek. The Lower Salmon and Lower Little Salmon subbasins support most grazing on the Nez Perce-Clearwater. The Nez Perce-Clearwater administers a relatively small portion of the lower Little Salmon subbasin, which mostly includes the Rapid River watershed. Some riparian reaches may be affected by streamside trails, dispersed camp sites, livestock grazing, and noxious weeds.

In the Lower Salmon and lower Little Salmon subbasins, 10 of the 22 sub-watersheds have road densities greater than 3 miles per miles squared (mi/mi^2), a level associated with worsening instream conditions. PACFISH and INFISH Biological Opinion (PIBO) assessed six managed sites in the Lower Salmon subbasin administered by the national forest, though only one site in the Little Salmon (Saunders et al. 2019a). All the metrics except one showed no departure from reference conditions (Table 124). Percent pools scored lower than reference conditions. Portions of this subbasin (Little Slate Creek drainage) have been heavily managed in the past, and Upper Little Slate Creek was also affected by mining. Cobble embeddedness was measured repeatedly under the former Forest Plan in the Slate Creek watershed and declined between 1988 and 1994 and between 2011 and 2016 (Thompson et al. 2019). Cobble embeddedness at the managed sites improved and came to resemble reference values. Of the nine metrics, most (five) showed no significant trend since PIBO monitoring began, while three (O.E., Large Wood Frequency, and D50) showed trends toward conditions observed at reference sites, and two (Uncut percent, Bank Angle) showed trends away from reference conditions (Table 125).

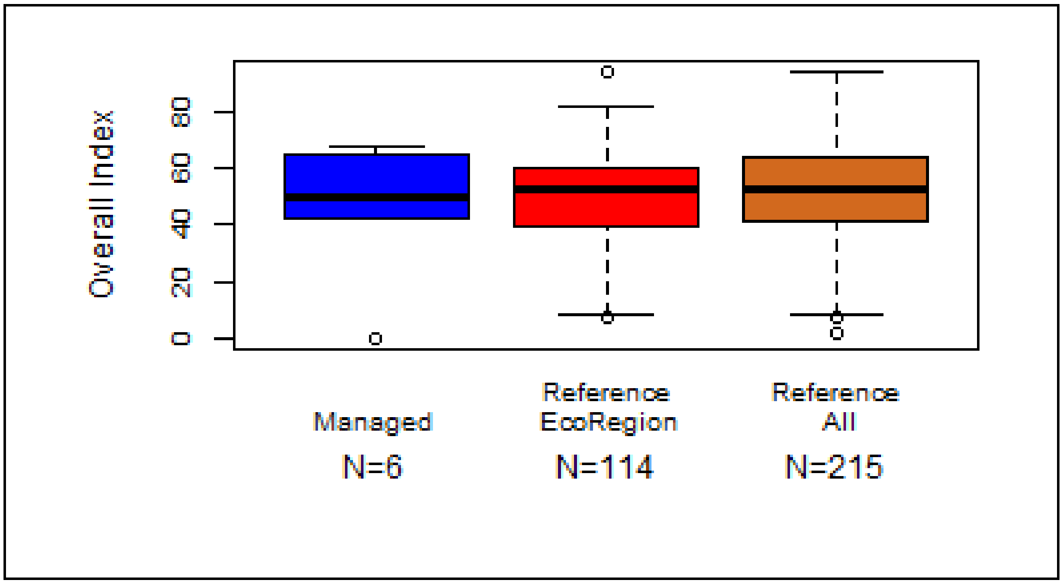

Figure 39. Overall index values in the Lower Salmon (Saunders et al., 2020). Median and range of index values for managed sites, reference sites within the ecoregion, and reference sites for the entire PACFISH and INFISH Biological Opinion (PIBO) study area.

Lower North Fork Clearwater Subbasin

Only 28 percent of the Lower North Fork Clearwater subbasin is managed by the Nez Perce-Clearwater. Riparian areas throughout the mainstem North Fork Clearwater River and its tributaries were affected by wildfires in the early 1900s. Road construction and timber harvest activities have decreased the riparian cover along many tributaries throughout the watershed. Mining, agricultural, and forestry activities have also changed the stream channel locations and morphology in some areas, particularly in watersheds with high percentages of mixed ownership, which includes nearly all of them. These changes have decreased the streamside shade, increased solar radiation to streams, increased sediment delivery, and generally decreased habitat complexity in streams. PACFISH and INFISH Biological Opinion (PIBO) sampling in this basin does not have a sufficient sample size to determine status and trends.

Upper North Fork Clearwater Subbasin

The Upper North Fork Clearwater HUC8 subbasin extends from the mouth of Beaver Creek up to the headwaters. The Nez Perce-Clearwater manages 93 percent of the subbasin. The Upper North Fork Clearwater was in the best overall condition on the national forests as summarized in the 2020 PIBO report Figure 43. One habitat metric (D50) scored higher than ecoregion reference benchmarks. One metric, pool depth, scored lower than reference values (Table 124). The overall trend since PIBO began was away from reference values; however the only individual metric that showed a significant trend was vegetation stability which moved toward reference conditions (Table 125).

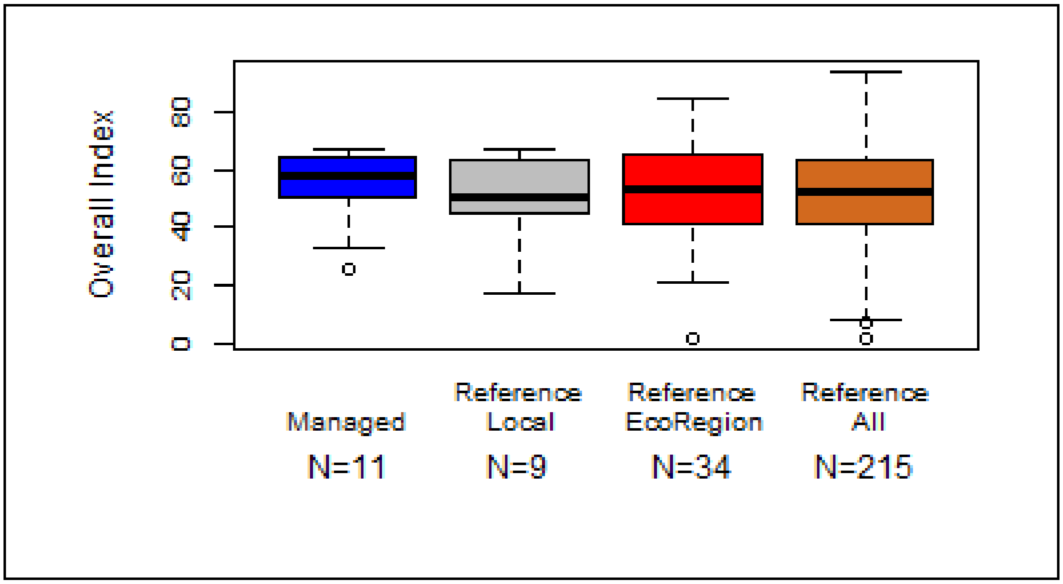

Figure 40. Overall index values in the Upper North Fork Clearwater (Saunders et al. 2020). Median and range of index values for managed sites, local reference sites, reference sites within the ecoregion, and reference sites for the entire PACFISH and INFISH Biological Opinion (PIBO) study area.

(Saunders et al. 2020)

Lochsa Subbasin

The Lochsa River joins the Selway River to form the Middle Fork Clearwater at Lowell, Idaho. The subbasin contains large portions of undeveloped forest land with 96 percent of the land base administered by the Nez Perce-Clearwater. Most of the Lochsa River is designated as a Wild and Scenic River and about half the subbasin south of the river is part of the Selway Bitterroot Wilderness Area.

Large fires occurred in the subbasin in 1910, 1919, 1924, and 1934 and may have occurred regularly before records were kept. Large fires have also occurred over the last 18 years, with many acres burning in 2000, 2007, and 2015. Some of these burned areas have not yet reforested and remain as brush fields. The combination of loose soils, steep slopes, and intense rain-on-snow events has produced landslides that dissect the subbasin with steep valleys and episodic delivery of sediment to streams. The subbasin landforms and the historic record confirm that these processes define the normal subbasin condition.

Road construction has created road densities of greater than 3 miles per miles squared (mi/mi^2) in 12 of 28 subwatersheds in this subbasin, likely reducing riparian cover and habitat quality. Larger streams in the Lochsa subbasin generally provide good to excellent spawning and rearing habitat.

Per the 2020 PACFISH and INFISH Biological Opinion (PIBO) report (Saunders et al. 2020), the Lochsa was the second least disturbed subbasin summarized (Figure 43). No metrics were significantly different than reference benchmarks (Table 124), though residual pool depths trended away from reference values over the measurement period, and O.E. significantly trended toward reference values (Table 125).

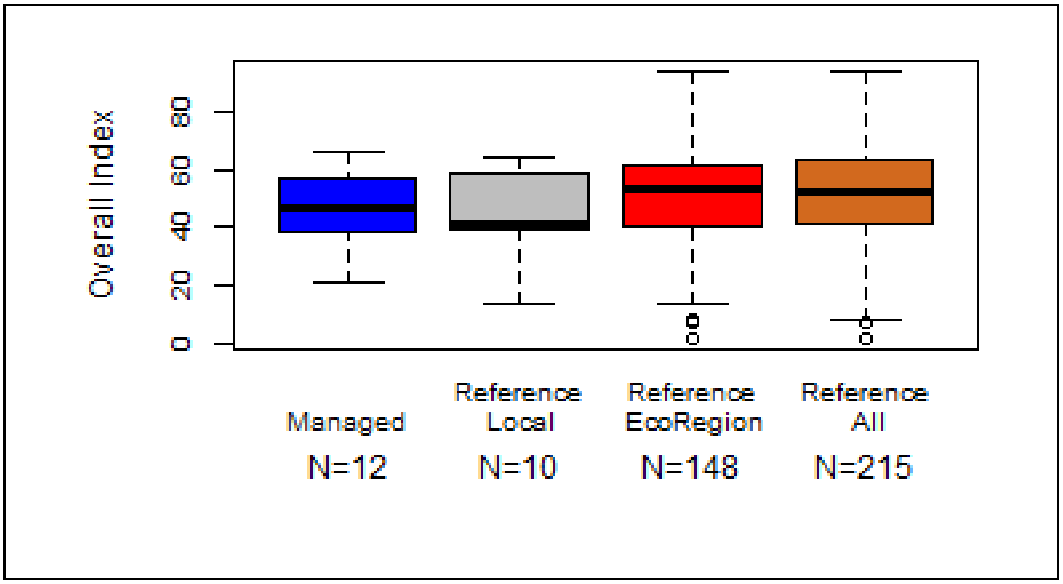

Figure 41. Overall index values in the Lochsa (Saunders et al. 2020). Median and range of index values for managed sites, local reference sites, reference sites within the ecoregion, and reference sites for the entire PACFISH and INFISH Biological Opinion (PIBO) study area.

The Forest Service Watershed Condition Class Assessment (U.S. Department of Agriculture 2011d) noted that of 38 HUC12s in the Lochsa, 29 (76 percent) were Properly Functioning, while nine were Functioning at Risk.

Selway River Subbasin

The Selway River extends from headwater areas administered by the Bitterroot National Forest to its confluence with the Lochsa River. Both the Upper and Lower Selway subbasins were priority watersheds under PACFISH/INFISH. Virtually all of the land in both subbasins is administered by the Forest Service.

Compared to the rest of the subbasins on the Nez Perce-Clearwater National Forests, the two Selway subbasins are the least disturbed by human development. Only two of the 43 subwatersheds have road densities above 2 miles per mile squared (mi/mi^2) and only four have road densities above 1 mi/mi^2. Available data from streams above the wilderness boundary are assumed to represent natural conditions and indicated very low levels of deposited sediment, such as percent fines below 10 percent and cobble embeddedness below 25 percent; moderate to high levels of large wood depending on channel gradient; and moderate to high habitat complexity, as indicated by the number of pools, large wood, diverse substrate composition, and diverse channel gradients (USDA-FS unpublished data, 1992 – 2003). In 2011, the Forest Service's Watershed Condition Class assessment (U.S. Department of Agriculture 2011d) noted that 42 out of 43 Selway HUC12s were Functioning Properly and one was Functioning at Risk. The Upper and Lower Selway subbasins do not have enough managed PACFISH and INFISH Biological Opinion (PIBO) sites to establish status, but the Lower Selway does have enough to determine trends of stream habitat attributes (Saunders et al. 2020). The overall index on the Lower Selway has trended toward reference conditions since PIBO began, as did the individual metrics D50 and large wood frequency (Table 125). All other metrics showed no significant trends.

Middle Salmon-Chamberlain Subbasin

The Nez Perce-Clearwater National Forests share the administration of the subbasin with the Payette and Bitterroot National Forests. The Payette National Forest administers National Forest System lands on the south side of the Salmon River while the Nez Perce-Clearwater National Forests administer the north side. The Bitterroot National Forest administers a portion of the north side. There is little private land.

Specific reaches of some watersheds have been affected by past and ongoing livestock grazing and mining activities. A substantial portion of the Middle Salmon-Chamberlain subbasin is within designated Wilderness or is roadless and riparian areas are largely unaffected by landscape scale human disturbances. The Middle Salmon-Chamberlain subbasin does not have enough managed PIBO sites to establish status or trend of stream habitat attributes (Saunders et al. 2020).

Middle Fork Clearwater Subbasin

The Middle Fork Clearwater subbasin is the smallest on the Nez Perce-Clearwater National Forests. Land ownership in this subbasin is comprised of private, state, federal, and tribal holdings. The national forests manage about 55 percent of the subbasin. Lands are generally heavily forested.

Clear Creek is a tributary to the Middle Fork Clearwater River and contains much of the stream habitat accessible to anadromous and resident fish in this subbasin. It has high habitat potential for spawning and early rearing for anadromous fish. In 2011, the Forest Service's Watershed Condition Class assessment (U.S. Department of Agriculture 2019a) noted that three of the four HUC12 watersheds in the Middle Fork were Functioning at Risk, and one was Properly Functioning.

Basin-wide surveys were conducted by contractor Stillwater Sciences in 2015 in the mainstem of Clear Creek and several tributaries, including Middle Fork Clear Creek, Brown Springs, Pine Knob, South Fork Clear Creek, and West Fork Clear Creek. Mean cobble embeddedness exceeded 30 percent across most surveyed reaches, although was less on reaches downstream of National Forest System lands (Stillwater Sciences 2015). Survey results indicated very low levels of large wood in many reaches, as well as other indicators of simplified habitat including low numbers of pools. Sediment levels that exceed desired conditions have likely affected the quality and quantity of habitat available for trout and salmon.

In 2015 and prior, the Clearwater National Forest contracted for six additional PIBO monitoring sites in Clear Creek, which is a tributary of the Middle Fork Clearwater (Archer and Ojala 2016). All of the metrics were not significantly different from reference conditions except large wood frequency, pool percent, and pool fines, which scored lower than reference sites. None of the metrics showed a significant change except bank angle, which moved away from reference conditions. (Archer and Ojala 2016). During the most recent sampling in 2019, the Middle Fork Clearwater subbasin did not have enough managed PACFISH and INFISH Biological Opinion (PIBO) sites to establish status or trends of stream habitat attributes (Saunders et al. 2020).

South Fork Clearwater Subbasin

The South Fork Clearwater contains a mix of ownerships, but the national forests administer over 88 percent of the land area. Many areas of the subbasin have been extensively managed.

When habitat indicators are combined for the overall index value, managed sites scored lower than ecoregion reference sites (Figure 42). Of the seven indicators used, five were not significantly different from current ecoregional reference sites, and two — pool depth and pool percent — scored lower than reference sites. The trend since PIBO began (Table 125) shows the overall index trending toward reference site values, as did D50. Table 124 shows P-values of PIBO status index values from forest sub-basins.

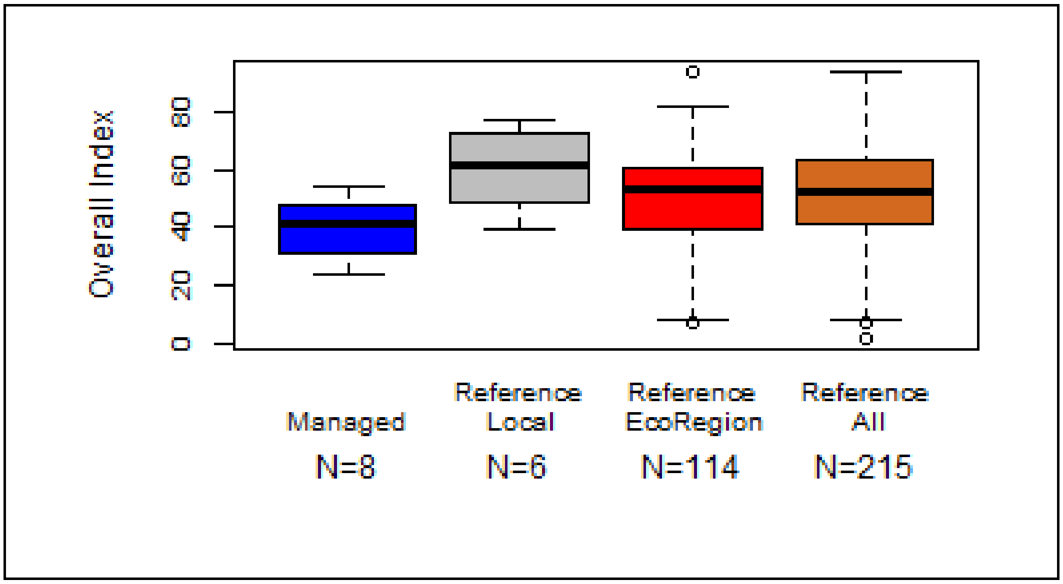

Figure 42. Overall index values in the South Fork Clearwater (Saunders et al. 2020). Median and range of index values for managed sites, local reference sites, reference sites within the ecoregion, and reference sites for the entire PACFISH and INFISH Biological Opinion (PIBO) study area.

Table 124. P-values associated with PACFISH and INFISH Biological Opinion (PIBO) status index values from managed sites at the subbasin scale on the Nez Perce-Clearwater Forest 2001 to 2019. P-values lower than 0.10 indicate a significant difference between managed sites and eco-regional reference sites

Managed Site	Overall	Pool Depth	Pool %	D_{50}	Pool Fines	Wood Freq.	Bank Angle	OE	Total Signif. Lower
Clearwater	<0.01[a]	0.81	0.29	0.09	0.03[a]	0.88	0.53	<0.01[a]	3
Lower Salmon	0.61	0.56	0.05[a]	0.3[a]	0.75	0.33	0.42	0.82	2

b= this value scored significantly higher than the eco-region reference value

PIBO Data Trends at the Sub-basin Scale

A similar approach to trends at the subbasin scale can provide insight into how effectively PACFISH and INFISH Biological Opinion (PIBO) standards are facilitating movement toward reference values (Table 125).

Table 125. P-values associated with PACFISH and INFISH Biological Opinion (PIBO) trends from managed sites at the subbasin scale on the Nez Perce-Clearwater Forest 2001 to 2019. P-values lower than 0.10 indicate a significant difference between 2001 and 2019 either toward or away from the desired direction. NC = no change.

Managed Site	Overall	Pool Depth	Pool %	D50	Pool Fines	LWD Freq.	Bank Angle	OE	Veg Stab.	Uncut %	Total Toward	Total Away	NC
Clearwater	0.42	0.93	0.86	0.71	1	0.93	0.88	0.16	<0.01[b]	0.11	0	1	9
Lower Salmon	0.75	0.12	0.35	0.04[a]	0.75	0.04[a]	0.04[b]	0.08[a]	0.17	0.08[b]	3	2	5

a= significant change toward desired direction

b= significant change away from desired direction

Overall, status index scores in each subbasin for which data was available were divided by their respective ecoregional reference score to obtain an index ratio to facilitate relative comparison of overall condition across subbasins. According to this analysis the Upper North Fork Clearwater was in the best overall relative condition, followed by the Lochsa, Lower Salmon, South Fork Clearwater, and the Clearwater (Figure 43).

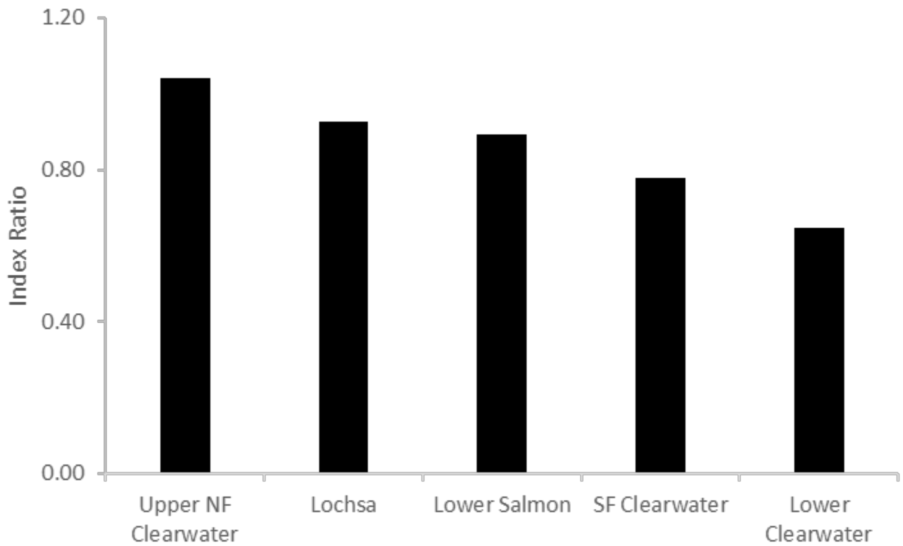

Figure 43. Ratio of 2020 PACFISH and INFISH Biological Opinion (PIBO) overall index score to ecoregional reference score for five subbasins on the Nez Perce-Clearwater National Forest. A value of 1 indicates equality with reference conditions.

Substrate Conditions Related to Sediment from Data Other Than PACFISH and INFISH Biological Opinion (PIBO)

Cobble Embeddedness – historic Nez Perce National Forest

The Nez Perce National Forest established a monitoring plan to evaluate the effectiveness of the Nez Perce Forest Plan in achieving aquatic objectives. The stream habitat and fish portion of this monitoring plan included periodic re-examinations of bio-physical conditions at 26 permanent monitoring reaches distributed across the Nez Perce National Forest. Stations were established in both managed and unmanaged reference watersheds and were located at lower elevations in watersheds, generally near the mouths of streams in reaches that were thought to indicate broader changes in habitat. In some cases, these stations were associated with gaging stations, and in all cases dominant geologic type—basalt, Idaho batholith, or belt—was identified.

Methodology and the results of cobble embeddedness monitoring are fully described in the Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a). The cobble embeddedness metric has served as a key indicator of stream conditions and habitat carrying capacity on the Nez Perce National Forest since the early 1980s. However, some concern that this indicator might not accurately represent conditions in some situations has been raised since the late 1990s (Sylte and Fischenich 2002). There was concern that it might not respond to the cessation of activities that caused the initial embeddedness, and that inconsistencies with how data was collected and analyzed could yield erroneous results. In order to provide a longer time series of monitoring data, the initial embeddedness monitoring that was completed from 1998 through the mid-1990s was repeated from

2011 through 2016 using the same protocols at a subset of monitoring locations. This ensured that the data could be reliably compared throughout both sampling periods.

In summary, results of the analysis suggest that statistically significant changes in measured mean cobble embeddedness have occurred and that it has declined since the mid-1990s in some streams on the Nez Perce National Forest. Streams in managed watersheds, including the Upper Red River, Lower Red River, Lower Newsome, Crooked River, O'Hara Creek, North Fork Slate Creek, and Little Slate Creek all exhibited decreased cobble embeddedness over time, as indicated by a comparison of data from 2011 to 2016 and 1988 to 1994. These sites are in watersheds with a history of human disturbance. Significant changes were not observed at unmanaged watersheds including Johns Creek and Upper Meadow Creek sites, although Lower Meadow Creek appears to indicate a statistically significant reduction in cobble embeddedness since the period of 1988 to 1994. These three sites are considered reference because they are in watersheds with minimal human disturbances.

These results are compelling for several reasons. First, a reduction in cobble embeddedness was observed at every managed site for which data was collected, substantially so for the Upper Red River, Lower Red River, Lower Newsome, and O'Hara sites. Second, dramatic declines in cobble embeddedness are not evident at the Johns or Upper Meadow reference sites, which display low levels of cobble embeddedness for all years when compared to the 1988 to 1994 data from the managed sites. These results suggest that land management practices implemented under the 1987 Nez Perce Forest Plan, as amended by PACFISH, were effective in reducing fine sediment in these streams.

The Lower Meadow site, however, did exhibit a statistically significant reduction in cobble embeddedness, possibly the result of cessation of human-caused disturbances since the early 2000s in the Horse Creek watershed, which enters Meadow Creek about two miles upstream of the site.

Percent Surface Fines and Fines by Depth – historic Clearwater National Forest

Similar to the Nez Perce National Forest, the Clearwater National Forest developed and implemented a monitoring plan to evaluate the effectiveness of the Clearwater Forest Plan in achieving aquatic objectives.

Long term monitoring data is available for the Lower Clearwater, Middle Fork Clearwater, and Palouse/Hangman subbasins on the Clearwater National Forest. The data is summarized in forest plan monitoring reports produced by the Clearwater National Forest from the 1990s through 2009. Deposited fine sediment was monitored using Wolman pebble counts to obtain an estimate of percent surface fines, and substrate core sampling was used to obtain an estimate of percent fines by depth. The complete methodology and analysis are included in the Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a).

In summary, substrate data collected in various watersheds across the Clearwater National Forest since the mid-1990s suggested that sediment conditions are improving in some places, improving more slowly than desired in other places, and not being responsive at all in a few places. For example, in Deadman and Pete King creeks, percent fines by depth in the last year they were measured were less than they were in the early 1990s, although inter-annual variation was high. In the Potlatch and Palouse River subbasins, available substrate monitoring data suggested either static conditions or slight declines, with surface fines levels remaining greater than 20 percent at all monitored sites, and in some cases substantially so. Surface fines appeared to be much lower in two sites in the Upper North Fork Clearwater, although it remained high in Elk Creek, a tributary of the Lower North Fork Clearwater River. However, it should be noted the number of monitored sites is small, and summarized data is only available up to 2009. Additional years of monitoring data would be helpful at these sites, as conditions may have changed since 2009; however, this is unlikely given current budget constraints, unless a cooperative monitoring program is established through partnerships with other stakeholders.

Summary of Trends in Stream Habitat across the Nez Perce-Clearwater

The information presented in previous sections suggests that improving trends have occurred in many watersheds since the last forest planning effort in 1987, but conditions in other watersheds may not have improved.

Espinosa et al. (1997) concluded the previous planning efforts and implementation of best management practices on the Clearwater National Forest failed to result in improved conditions in some of its most degraded watersheds, including Lolo, Eldorado, and Pete King creeks. Their publication, however, only considered data and information available through 1995, which was prior to PACFISH and INFISH amending the Clearwater Forest Plan. The previous discussion regarding trends, as well as the following assessment of Land Management Plan effectiveness, includes the older data, plus more contemporary data including PACFISH and INFISH Biological Opinion (PIBO).

For the Nez Perce National Forest, an improving trend is indicated by both forest plan monitoring substrate data at managed sites, as well as PIBO data, particularly in the South Fork Clearwater subbasin. At forest plan monitoring sites in managed watersheds, decreases in cobble embeddedness were evident from 1988 to 2016. Most notable among the decreases were sites in Red River and Newsome Creek. The 1987 Nez Perce Forest Plan identified these watersheds as the Nez Perce National Forest's "priority drainages" and specified that "management-derived sediment which could affect fish habitat will not be allowed until monitoring indicates habitat has recovered to plan levels." Cessation of large-scale development combined with watershed restoration activities initiated in the early 1990s and continuing through 2016, especially those associated with removal of chronic sediment sources, reduced overall sediment yield. This reduction is correlated with improved substrate conditions.

In the Lower Selway subbasin, PIBO data indicates a statistically significant improving trend in the overall index. One forest plan monitoring site in O'Hara Creek, a large, managed watershed below Selway Falls, indicates lower levels in cobble embeddedness from 2011 to 2016 when compared to 1988 to 1995. In the Salmon River subbasins, forest plan monitoring station data suggests substrate conditions may have improved from the early to mid-1990s to 2012 at two sites, both of which are located in the Slate Creek drainage of the Lower Salmon subbasin. Portions of Slate Creek have been heavily managed in the past, particularly Little Slate Creek.

In summary, available information suggests that implementation of land management planning under the Nez Perce Forest Plan, as amended by PACFISH, was successful at preventing long-term management-caused degradation in most watersheds on the Nez Perce National Forest. In addition, available information indicates substrate conditions in many, if not most, managed watersheds on the Nez Perce National Forest have improved since 1988, although the degree of improvement is variable. Improvement in Red River stream substrate conditions is most notable, considering very high levels of deposited fine sediment evident in the mid-to-late 1980s. This improvement is likely a combination of cessation of new permanent road construction and aggressive implementation of aquatic restoration from the 1990s to present. The requirement in the Nez Perce Forest Plan Appendix A to initiate an upward trend in habitat carrying capacity in degraded watersheds, combined with limits on sediment yield and entry frequency and standards and guidelines included in the PACFISH amendment, appear to have been effective in meeting the objective of improving degraded stream habitat, although in most cases streams remain below their objectives, and in many cases are less favorable than reference reaches, but are trending towards them.

For the Clearwater National Forest, substrate data collected in various watersheds across the Clearwater National Forest since the mid-1990s suggests that sediment conditions are improving in some places and improving more slowly than desired in other places. In some places, available data has not detected any improvement.

PACFISH and INFISH Biological Opinion (PIBO) monitoring data for the Lower Clearwater subbasin from 1999 through 2019 indicates stream conditions in managed watersheds are static and remain in a degraded condition when compared to reference. Median substrate, and macroinvertebrate index, both indicators of substrate condition, remain outside of ecoregional reference conditions in sampled reaches on the Nez Perce-Clearwater. However, trend data for this subbaasin indicates that vegetation stability has improved since 1999.

PIBO monitoring data from the Lochsa subbasin, conversely, suggests some habitat attributes have improved during the study period from 1999 to 2019. Even though trends are positive for some indicators, substrate conditions measured by the PIBO protocol appear to be static. The overall trend in PIBO data from the Upper North Fork Clearwater subbasin suggests conditions may have degraded since 1999, although overall conditions remain within the range of reference based on data through 2019.

Examination of departures from reference conditions of status scores at the subbasin scale can help to explain overall index scores by identifying either problem basins or common metrics across the national forest that need improvement (Table 124). For this exercise, the overall index value was included, as it is derived independently of the individual stream attributes and is informative in its own right. Two subbasins, the Lower Clearwater and South Fork Clearwater, each had three metrics that scored significantly lower than ecoregional reference sites, although they were different sets of metrics. The Lower Salmon had two metrics that showed departure, the Upper North Fork Clearwater showed two (one that scored lower and one that scored higher), and the Lochsa did not have any metrics that were different from reference conditions. Of those that were significantly departed, none of the metrics scored significantly lower across all subbasins, indicating that there are not standard problems across the national forest related to one metric. In addition, all the subbasins were not different from reference condition for most metrics. This indicates that "managed" watersheds exhibit a wide range of management effects, and that as a result, stream metrics differ among monitored watersheds.

From 2001 to 2019, most subbasin metrics across the Nez Perce-Clearwater (45 out of 60) had not changed significantly, indicating that in most places, and for most metrics, there has been a lack of degradation since the implementation of PIBO. Of those that did, most (10 out of 15) have been in the desired direction. All the subbasins showed more metrics trending toward desired conditions than away from desired conditions. Of those basins that exhibited trends away from desired conditions, only one (Lower Salmon) showed trends away from desired conditions in more than one metric.

In summary, available information suggests that implementation of land management planning under the Clearwater Forest Plan, as amended by PACFISH and INFISH, succeeded at preventing long-term management-caused degradation in most watersheds on the Clearwater National Forest. Improving trends are indicated in some areas on the Clearwater National Forest where focused aquatic restoration efforts have been implemented, including road decommissioning and riparian fencing. In addition, improvement has also occurred in areas where the implementation of standards and guidelines for roads and riparian habitat conservation areas (RHCAs) arrested continued degradation and facilitated passive restoration.

Aquatic Species

Fish

The Nez Perce-Clearwater supports four fish species that are federally listed as threatened under the Endangered Species Act (ESA) and one species that is listed as endangered. One fish Species of Conservation Concern has been identified on the Nez Perce-Clearwater, and one focal aquatic species has been identified. All are more fully described in the following text, with other aquatic species of interest, and non-native species are identified as well. Species on the regional forester's sensitive species list are also described.

Endangered Species Act Listed Fishes

Snake River Spring/ Summer Chinook Salmon (*Oncorhynchus tshawytscha*)

Status and Distribution: Spring and summer Chinook are two of three ecotypes (commonly called runs) of Chinook that occur in Idaho and are classified by seasonal designations reflecting when adult Chinook enter freshwater to begin their spawning migration. Spring and summer Chinook spawn and rear in most rivers on the national forest (Clearwater, Lochsa, Selway, Salmon) and their larger tributaries. The Snake River spring and summer Chinook Salmon Evolutionarily Significant Unit (ESU) was listed as Threatened on April 22, 1992 (57 FR 27160); Threatened status was reaffirmed May 26, 2016 (81 FR 33468) and July 26, 2022 (National Oceanic and Atmospheric Administration 2022b). The Snake River spring and summer Chinook Salmon ESU includes all naturally spawned populations of spring and summer Chinook salmon originating in the mainstem Snake River and the Tucannon River, Salmon River, Grande Ronde River, and Imnaha River). On June 28, 2005, National Oceanic and Atmospheric Administration Fisheries announced a final policy addressing the role hatchery origin salmon and steelhead in listing determinations under the ESA (70 FR 37204, Hatchery Listing Policy):

"This policy establishes criteria for including hatchery stocks in ESUs and [distinct population segments] DPSs. In addition, it:
(1) provides direction for considering hatchery fish in extinction risk assessments of ESUs and DPSs;
(2) requires that hatchery fish determined to be part of an ESU or DPS be included in any listing of the ESU or DPS;
(3) affirms our commitment to conserving natural salmon and steelhead populations and the ecosystems upon which they depend; and
(4) affirms our commitment to fulfilling trust and treaty obligations regarding the harvest of Pacific salmon and steelhead populations, consistent with the conservation and recovery of listed salmon ESUs and steelhead DPSs" (National Oceanic and Atmospheric Administration 2022a).

The Snake River spring and summer Chinook ESU now includes wild fish as well as fish cultivated from 14 specific hatchery programs, including the Tucannon River Program, Lostine River Program, Catherine Creek Program, Lookingglass Hatchery Program, Upper Grande Ronde Program, Imnaha River Program, Big Sheep Creek Program, McCall Hatchery Program, Johnson Creek Artificial Propagation Enhancement Program, Pahsimeroi Hatchery Program, the Sawtooth Hatchery Program, the Yankee Fork Program, the Dollar Creek Program, and the Panther Creek Program (70 FR 37159; 85 FR 81822). Spring and summer Chinook salmon in the Clearwater basin are not ESA listed or included in this ESU.

Endangered Species Act (ESA) listed Snake River spring and summer Chinook salmon on the Nez Perce-Clearwater are part of two major population groups, which include the South Fork Salmon River and the Middle Fork Salmon River. These major population groups are broad geographic groupings that include populations outside their named river basins. Populations with spring and summer Chinook salmon spawning and rearing on the Nez Perce National Forest include the Little Salmon population and the Chamberlain population, both of which are considered intermediate populations based on historical habitat potential (Interior Columbia Basin Technical Recovery Team 2003). Spring and summer Chinook salmon are distributed throughout the Salmon River and several tributaries, including the Wind River and Crooked Creek, and Bargamin Creek, as shown in the distribution maps in Appendix A.

Under the Magnusen-Stevens Act, as amended, the spawning and rearing habitat provided by rivers and streams on the Nez Perce-Clearwater, are designated as part of the Essential Fish Habitat for Chinook salmon.

Snake River Spring/Summer Chinook populations, like many anadromous fish on the forest, declined starting in the 1800's, due primarily to overfishing and lower productivity from loss of associated marine derived nutrients (Gresh 2000). This decline continued into the 1900's, exacerbated by land use practices. A much smaller decline occurred mid-century, leading to the ESA listing in 1992. Some have hypothesized that this decline was a direct result of the construction of the four lower Snake river dams in the 1970's, however, as noted by (Vendetti 2015), "this line of reasoning does little to explain the concurrent declines in relatively free flowing coastal systems". Further discussion of the coast-wide decline in Chinook populations is found in Atlas et al. 2023, Another explanation is be tied to several regime shifts (Rocha et al. 2015) in the Pacific Ocean in the 1970's and late 1980's (Stephens et al. 2001, Noakes and Beamish 2009) that likely impacted food webs for Snake River Spring/Summer Chinook and other western North American Chinook stocks during their marine residence (Anderson and Piatt 1999). Large-scale drivers such as this have much greater potential to cause population level effects across a wide geographical range than localized events. For example, a similar ocean regime shift is currently contributing to the collapse of a whale population in the North Atlantic (Meyer-Gutbrod et al. 2021).

Felts et al. (2019) reported that results from 2017 monitoring efforts indicate Idaho populations of spring and summer Chinook Salmon are functioning at low abundance relative to historical observations and recovery goals. The most recent status reviews for the Snake River spring and summer Chinook Salmon Evolutionary Significant Unit (ESU) concluded the majority of populations in the ESU were at a high overall risk and recommended no change in status (NOAA 2022, NOAA 2023). Low productivity has been observed since the 2015 status assessment, resulting in a decreased abundance throughout the ESU. Unprecedented warm sea surface temperatures in the Pacific Ocean caused by a major marine North Pacific Heat Wave from 2014 to 2016 (Bond et al. 2015), and in 2019 (Amaya et al. 2020), have been a major driver of recent downward Chinook population trends (NOAA 2022). Idaho populations exhibit a great deal of synchrony with other populations of West Coast salmon and steelhead (Dorner et al. 2017, Kilduff et al. 2015, Mantua 2015, Welch et al. 2021), and spring and summer Chinook Salmon likely remain at a low abundance, and ESA listed populations continue to be considered at a high overall risk as long as ocean conditions are poor. Changes in density independent factors (such as sea surface temperature) which affect productivity could quickly reverse downward trends. As noted by Idaho Department of Fish and Game (IDFG), "Chinook Salmon have a high maximum annual reproductive rate (Myers et al. 1999), meaning populations can quickly increase in abundance when exposed to favorable conditions" (Poole et al. 2022). In 2020 and 2021, ocean conditions began to improve[16] and population index increases were seen. However, 2022 ocean conditions, while still good, were not as strong as 2021[17]. Snake River Spring and summer Chinook abundance on the Nez Perce Clearwater national forest is expected to continue to fluctuate, increasing when ocean conditions remain favorable, and decreasing when they are unfavorable.

In addition to ocean conditions, there is evidence that other major factors likely producing population level effects to Chinook salmon (both abundance and age structure) are ocean mortality through predation by resident orcas (*Orcinus orca*) (Ohlberger et al. 2019) and salmon sharks (*Lamna ditropis*) (Seitz et al 2019, Manishin et al. 2021), as well as estuarine predation by pinnipeds (Chasco et al. 2017, Thomas et al. 2016). The ESA recovery plan continues to list several freshwater factors as limiting to this ESU, including degraded habitat, simplified stream channels, disconnected floodplains, impaired instream flow, and loss of cold water refugia. For more discussion of relative threats to salmonids and how they relate to forest activities, see the discussion in the environmental consequences section of this document.

Idaho Department of Fish and Game (IDFG) conducts spring and summer Chinook index redd (spawning nest) counts in Idaho to monitor trends by major population group (MPG). This information was summarized by Copeland et al. (2019), through 2018, and updated data was provided by IDFG through 2022 (Figure 44)Figure 44. The Nez Perce-Clearwater supports habitat for a portion of the Salmon River MPGs.

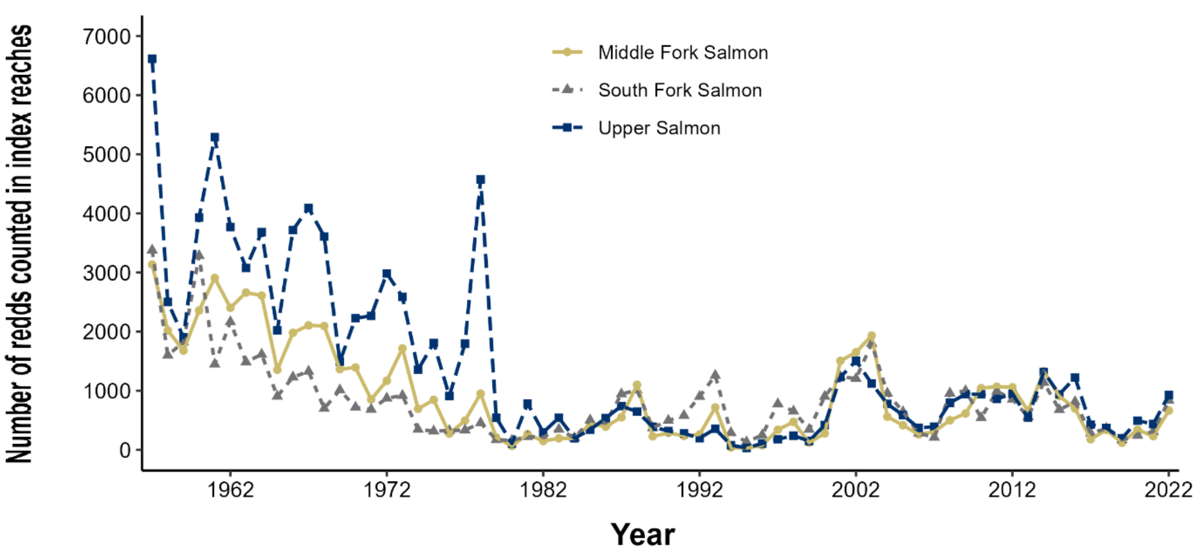

Figure 44. Snake River spring and summer Chinook salmon index redd count trends in Idaho, by major population group from 1966 to 2022. (Data from IDFG)

[16] (https://www.fisheries.noaa.gov/west-coast/science-data/ocean-indicators-summary-2020, https://www.fisheries.noaa.gov/west-coast/science-data/ocean-indicators-summary-2021)
[17] (https://www.fisheries.noaa.gov/west-coast/science-data/2022-summary-ocean-ecosystem-indicators)

Chinook salmon are currently identified as a management indicator species under both the 1987 Nez Perce and Clearwater Forest Plans, as amended.

Designated Critical Habitat: Critical habitat for Snake River spring and summer Chinook salmon was designated on December 28, 1993 (Federal Register, Vol. 58, 68543), effective on January 27, 1994. Critical habitat is the specific areas within the geographic area, occupied by the species at the time it was listed, that contain the physical or biological features that are essential to the conservation of endangered and threatened species and that may need special management or protection. Critical habitat may also include areas that were not occupied by the species at the time of listing but are essential to its conservation.

Snake River Steelhead Trout (*Oncorhynchus mykiss*) & Redband Trout (*Oncorhynchus mykiss gairdneri*)

Status and Distribution: Steelhead and redband trout are present throughout the Salmon and Clearwater basins and in most tributaries that are accessible and of sufficient size to support fish. Although classified as the same subspecies, the term "steelhead" generally refers to the anadromous form, while "redband trout" refers to the stream resident form that does not migrate to the ocean (Behnke 1992). These two life histories are just two of many complex life histories expressed by *O. mykiss* (Behnke 2002). When they occur together in a stream, they often interbreed, and progeny from the same parents can exhibit either resident or anadromous life histories (Sloat and Reeves 2014, Courter et al. 2013). Because of these factors, and the difficulty in distinguishing between anadromous and resident fish in the juvenile stage (Thurow 1997; 2007), the term interior redband trout almost always refers to resident redband that are above impassable barriers or outside the range of anadromy (Mulfeld et al. 2015, Thurow et al. 1997). In the Snake River basin, only anadromous steelhead are Endangered Species Act (ESA) listed, while interior redband are not. Because the two life histories are indistinguishable where sympatric, sport fisheries in anadromous waters preclude non-tribal sport harvest of naturally produced fish (as evidenced by intact adipose fin) exhibiting either life history. Tribal anglers are allowed to harvest both clipped (hatchery produced) and some unclipped fish (naturally produced), with unclipped fish being authorized under an ESA take permit. The Snake River Steelhead Distinct Population Segment includes the anadromous form only and is currently listed as threatened under the ESA as of August 18, 1997 (62 FR 43937) and January 5, 2006 (71 FR 833); updated April 14, 2014 (79 FR 20802) and July 26, 2022 (United States National Oceanic and Atmospheric Administration 2022). The steelhead that spawn and rear in the Salmon and Clearwater basins on the Nez Perce-Clearwater are included in this distinct population segment.

The Snake River Basin steelhead distinct population segment (DPS) includes all anadromous populations that spawn and rear in the mainstem Snake River from its mouth to Hells Canyon Dam, and all tributaries except the North Fork Clearwater River above Dworshak Dam, which was completed in 1973. Following the final rule on including hatchery salmon and steelhead (85 FR 81822), the DPS now includes six hatchery programs, including Tucannon River, Dworshak National Fish Hatchery, East Fork Salmon River Natural, Little Sheep Creek/Imnaha, Salmon River B-run, and South Fork Clearwater B-run. The Snake River Basin steelhead distinct population segment is organized into six major population groups (five extant, one extirpated) that are subdivided into 26 populations (two of which are functionally extinct, leaving 24 remaining populations) (Interior Columbia Basin Technical Recovery Team 2003). The major population groups are defined by the following drainage basins: 1) Grande Ronde River, 2) Imnaha River, 3) Clearwater River, 4) Salmon River, 5) Hells Canyon Snake River, and 6) Lower Snake River. The Clearwater and Salmon River MPGs are those within the plan area. The Clearwater major population groups include six independent populations: the historic North Fork Clearwater (extinct), Clearwater River lower mainstem, Lolo Creek, Lochsa River, Selway River, and South Fork Clearwater River. Portions of these populations are located on the Nez Perce-Clearwater. The Lochsa, Selway, and Potlach rivers are managed as wild steelhead refuge areas with no hatchery releases or supplementation occurring within them (Idaho Department of Fish and Game 2013a). Clearwater River steelhead tend to spend an additional year in the ocean and return as larger B-run fish, while fish returning to the Snake and Salmon rivers tend to return earlier, and those populations are primarily classified as A-run fish. Wild steelhead returns from the Clearwater River major population group (MPG) are estimated annually by Idaho Department of Fish and Game (IDFG) using genetic stock indexing (GSI) of fish collected at Lower Granite Dam on the Snake River (Figure 45).

The Salmon River major population group includes portions of two independent populations out of a total of 12 that are found on the Nez Perce-Clearwater – the Lower Salmon River and Little Salmon River population and the Salmon River and Chamberlain population. Wild steelhead returns from the Salmon River MPG are estimated annually by IDFG using GSI of fish collected at Lower Granite Dam on the Snake River (Figure 46).

Populations in the Snake River Evolutionary Significant Units (ESUs) have mostly experienced declines since 2015, largely due to the same factors (warm sea surface temperatures) driving declines in spring and summer Chinook (National Oceanic and Atmospheric Administration 2022b). However, improved ocean conditions in 2020 and 2021 likely contributed to modest increases in wild adult steelhead returns to Lower Granite Dam observed in 2020, 2021 in Salmon River fish, and 2021 in Clearwater River fish (Figure 45 and Figure 46)). Positive responses in dam counts were presumably seen earlier in Salmon River fish because they tend to return to freshwater a year prior to Clearwater River fish.

Steelhead on and originating from the Nez Perce-Clearwater form a nationally renowned sport fishery of considerable socioeconomic importance, attracting anglers from all over the western United States and beyond. Spawning and rearing habitat provided by rivers and streams on the Nez Perce-Clearwater, along with large scale hatchery supplementation, are of utmost importance to the persistence and recovery of this species. The distribution of steelhead across the Nez Perce-Clearwater can be found on the steelhead distribution maps in Appendix A of the Final Environmental Impact Statement. Figure 45 and Figure 46 show the number of wild steelhead returns to the Clearwater and Salmon River Basins from 2009 to 2021, as well as the relative contribution of the different major population groups.

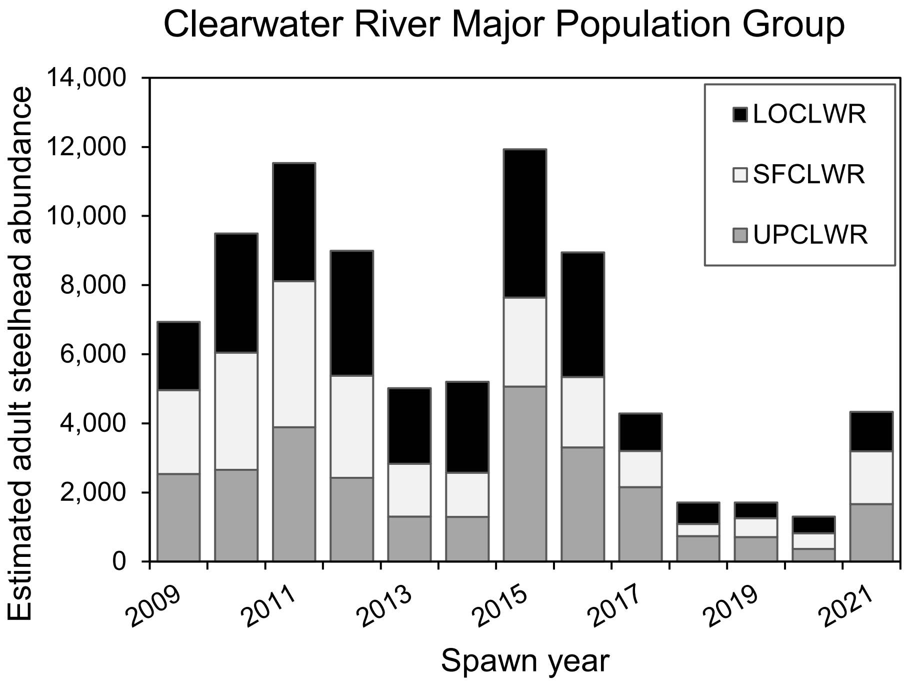

Figure 45. Wild steelhead returns in the Clearwater Basin, 2009 to 2021. Abbreviations are as follows: LOCCLWR is Lower Clearwater River, SFCLWR is South Fork Clearwater River, UPCLWR is Upper Clearwater River. Data from IDFG.

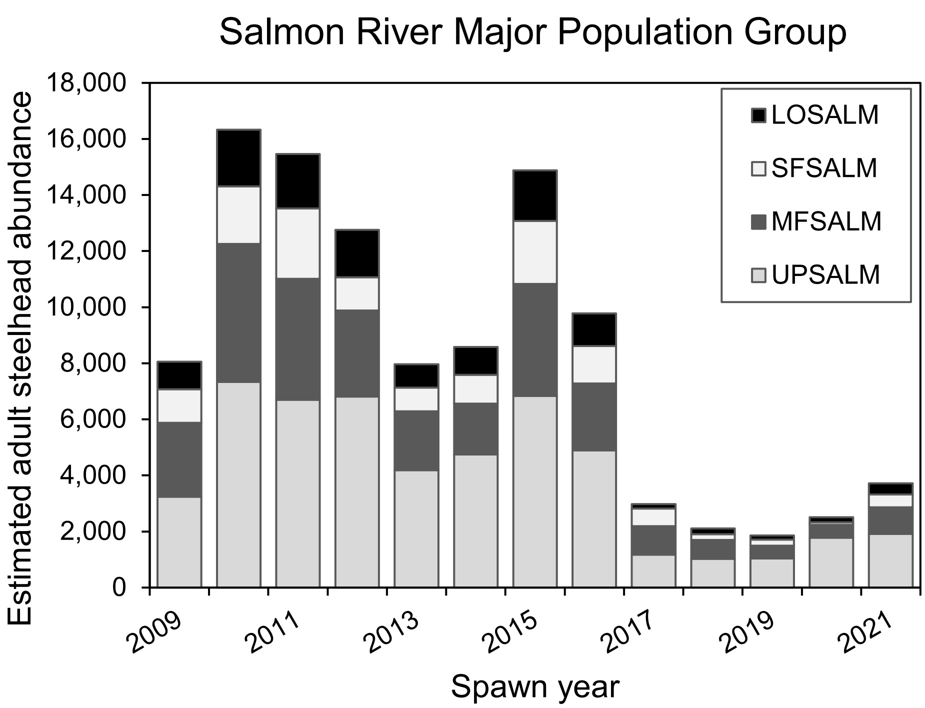

Figure 46. Wild steelhead returns in the Salmon River Basin, 2009 to 2021. Abbreviations are as follows: LOSALM is Lower Salmon River, SFSALM is South Fork Salmon River, MFSALM is Middle Fork Salmon River, UPSALM is Upper Salmon River. Data from IDFG.

Steelhead are currently identified as a management indicator species under both the 1987 Nez Perce and Clearwater Forest Plans, as amended.

Designated Critical Habitat: Critical habitat has been designated for the Snake River distinct population segment and includes the Potlatch, Clearwater, Lochsa, Selway, Middle Fork Clearwater, South Fork Clearwater, main Salmon River, and Little Salmon River mainstems in their entirety, in addition to accessible tributaries on the Nez Perce-Clearwater. Specific reaches were designated as critical habitat are outlined in Federal Register Vol. 70, No. 170 on September 2, 2005. See map in Appendix A.

Snake River Fall Chinook Salmon (*Oncorhynchus tshawytscha*)

Status and Distribution: Snake River fall Chinook salmon were listed as a threatened species under the Endangered Species Act on May 22, 1992 (Federal Register, Vol. 57, 14653).

Fall Chinook salmon migrate and spawn in the mainstem Snake, Salmon, and Clearwater rivers. Spawning has also been documented in the Middle Fork Clearwater, South Fork Clearwater, and Selway Rivers, as well as the lowest reaches of the Potlatch River. The U.S. Fish and Wildlife Service, The Nez Perce Tribe, and Idaho Power Corporation have conducted aerial and deep-water counts of fall Chinook redds in the Snake, Salmon, and Clearwater rivers since 1991. Since then, during most years, the majority of redds are counted in the Snake River below Hells Canyon Dam. During seven out of 31 years, there have been slightly more redds counted in the Clearwater River, due to supplementation efforts in that basin by the Nez Perce Tribe (Figure 47). Limited spawning and rearing by fall Chinook salmon occur in the Imnaha and Grande Ronde Rivers outside the boundaries of the Nez Perce-Clearwater.

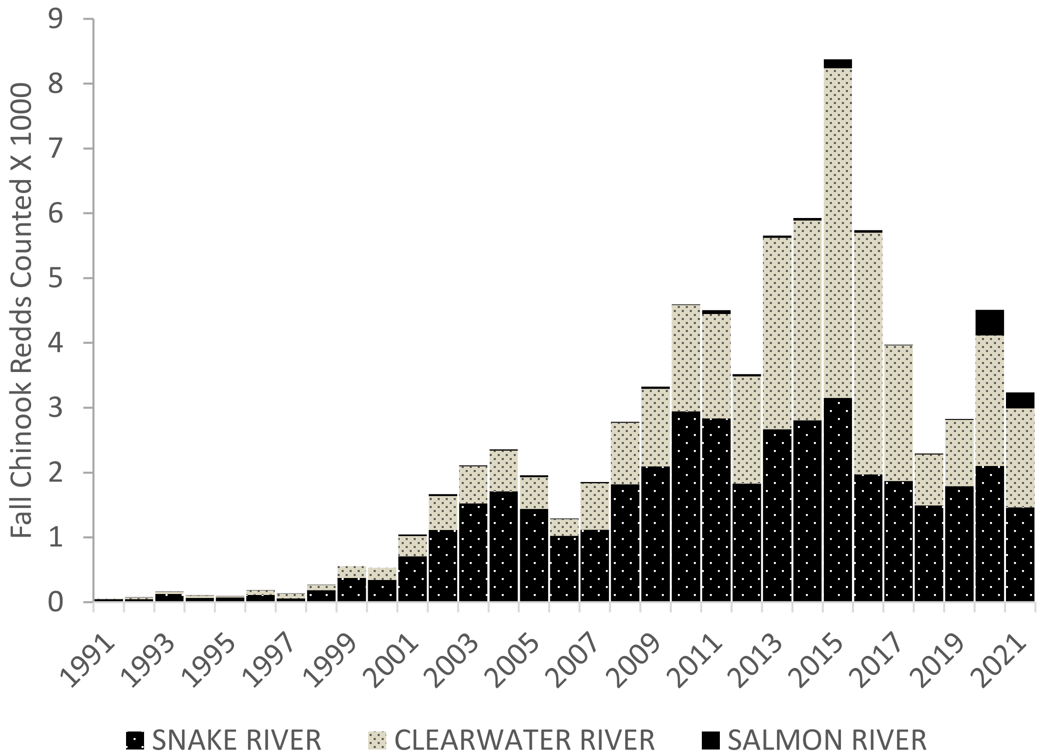

Figure 47. Aerial and deep-water Fall Chinook redd counts in rivers on or adjacent to the Nez Perce-Clearwater National Forest from 1991 to 2021. Data collected by U.S. Fish and Wildlife Service, Nez Perce Tribe, and Idaho Power Corporation

The Recovery Plan for Snake River fall Chinook salmon (National Oceanographic and Atmospheric Agency 2017) serves as a blueprint for the protection and recovery of Snake River fall-run Chinook salmon. It outlines the history of the species for each of seven tributary major spawning areas (MaSA):Tuncannon, Imnaha, Lower Salmon, Lower Clearwater, Grande Ronde, and two Snake River MaSAs. Two of these occur on or adjacent to the national forest: the Clearwater MaSA and the Salmon River MaSA. The recovery plan describes the current status, threats, and intended methods for increasing population sizes. The following is from the recovery plan concerning the Lower Clearwater River Major Spawning Area relevant to Snake River fall Chinook salmon (National Oceanic and Atmospheric Administration 2017).

“The Clearwater major spawning area] includes the 110-mile reach of the mainstem Clearwater River upstream from its confluence with the Snake River at Lewiston, Idaho, to Selway Falls and the lower reaches of the South Fork Clearwater, Middle Fork Clearwater, Potlatch, and Selway rivers. Snake River fall Chinook salmon return to the Clearwater subbasin from late August through December. Most of the [Clearwater River] fish spawn in the lower mainstem Clearwater below the confluence with the North Fork. However, spawning adults have been observed throughout the mainstem Clearwater River, the Middle Fork Clearwater River, and in the lower portions of the Potlatch, South Fork Clearwater, and Selway rivers. Spawning habitat is not considered a limiting factor for fall Chinook salmon in the lower Clearwater River but the impact of degraded water quality conditions could impact fall Chinook salmon spawning and rearing in the South Fork Clearwater River, Selway River, and other spawning areas.”

The recovery plan contains the following concerning the Lower Salmon River major spawning area:

"Data from 2000-2014 redd counts indicate that the lower Salmon River contributes a small percentage (0.8 percent ± 0.1 percent) of the basin-wide Snake River redd counts… Limited information exists on potential factors that could be limiting fall Chinook salmon use of the lower Salmon River. The lower Salmon River flows through both private and public lands, draining steep forested mountain slopes and then shrubs and grasses along the Salmon River canyon. Habitat conditions in the lower Salmon River and lower South Fork Salmon River are affected by excess fine sediment and reduced riparian vegetation from land use activities on adjacent lands and in upstream areas. Water temperatures drop in the lower Salmon River during the fall, and the plume created by cold water from the Salmon River where it enters the Snake River can provide thermal refugia for fall Chinook salmon."

Designated Critical Habitat: Critical habitat was designated on December 28, 1993 (Federal Register, Vol. 58, No. 247, p 68543), effective on January 27, 1994. Designated critical habitat for Snake River fall Chinook includes all Columbia River estuarine areas, the Columbia and Snake rivers, all Snake River reaches upstream to Hells Canyon Dam, the Palouse River up to Palouse Falls, the Clearwater River from its confluence with the Snake River upstream to its confluence with Lolo Creek, and the North Fork Clearwater River from its confluence with the Clearwater River upstream to Dworshak Dam, and the Lower Salmon subbasin. All HUC8 subbasins managed by the Nez Perce-Clearwater except for the Upper and Lower North Fork Clearwater are Essential Fish Habitat (EFH) for Chinook salmon under the Magnuson-Stevens Act (1976, as amended). There were 5-year status reviews released by National Oceanic and Atmospheric Administration fisheries in 2016 (National Oceanic and Atmospheric Administration 2016) and 2022 (National Oceanic and Atmospheric Administration 2022a), and the most recent one determined that listed status was still warranted still warranted, and that although the extant population met viability criteria, and extinction risk had improved and was low, that the Evolutionary Significant Unit (ESU) was still not meeting recovery goals.

Columbia River Bull Trout (*Salvelinus confluentus*)

Status and Distribution: Bull trout are present throughout the Clearwater and Salmon River basins and spawn and rear in many tributaries. Bull trout in these basins are included in the Columbia River bull trout distinct population segment, which was listed as threatened under the Endangered Species Act in 1998 (Federal Register Vol. 63 No. 111, p 31647). A 5-year status update was completed in 2008 (USFWS 2008) and 2015 (USFWS 2015), and another status update is currently underway (March 11, 2020 85 FR 14240).

Life history strategies present on the Nez Perce-Clearwater include resident, fluvial, and adfluvial. A significant adfluvial population is located in the North Fork Clearwater River (Hanson et al. 2014). It developed following construction of Dworshak Dam and establishment of Dworshak Reservoir. Two smaller potential adfluvial populations were thought to be associated with high mountain lakes, coincidentally both named Fish Lake. Fish Lake #1 is located in the Upper North Fork Clearwater subbasin and Fish Lake #2 is located in the Lochsa subbasin. Both populations are small. Although both populations have previously been thought to be adfluvial (CBTRT 1998), data from Idaho Department of Fish and Game (IDFG) suggests that Fish Lake #1 bull trout may be resident rather than adfluvial (Schriever and Schiff 2001 *in* NPCC 2003). There is currently ongoing genetic research at the University of Idaho that intends to help identify the life histories of bull trout residing in this lake. Preliminary results of that research indicate that bull trout in Fish Lake #1 are a small resident population (Alexandra Fraik, USFS, personal communication).

Fluvial populations are present in the Lochsa, Selway, South Fork Clearwater, Lower Little Salmon, and Middle-Salmon Chamberlain subbasins. In the Lower Salmon, there is one watershed in which fluvial bull trout are known to spawn and rear, Van Buren Creek, which is a high elevation stream in the Slate Creek watershed. A large fluvial bull trout population is also present in Rapid River, in the Lower Little Salmon subbasin. The status of bull trout distribution across the Nez Perce-Clearwater can be found on the bull trout distribution maps in Appendix A.

Both the Salmon Mid-Columbia Recovery Unit and Upper Snake Recovery Unit are designated as recovery units by the U.S. Fish and Wildlife Service for this distinct population segment, as well as local populations and potential local populations. A local population is defined as a group of bull trout using spawning and rearing habitat in stream complexes where there is a high probability of mating between these same individuals. A potential local population is defined as a population that may inhabit a stream complex, but sufficient data is lacking.

Bull trout are currently a management indicator species under the 1987 Clearwater Forest Plan, as amended. Bull trout are not a focal species under the new Land Management Plan, because focal species cannot be Endangered Species Act (ESA) listed.

In November 1999, all populations of bull trout were listed by the U.S. Fish and Wildlife Service within the coterminous United States as a threatened species pursuant to the ESA of 1973, as amended (U.S. Department of the Interior 2015c). The Columbia River distinct population segment occurs throughout the entire Columbia River basin within the United States and its tributaries. Critical habitat was designated for bull trout in 2010.

Bull trout core areas within the Clearwater River likely contain some of the most robust populations within the Lower Snake Region of the Mid-Columbia Recovery Unit. Most core areas within the Clearwater River basin are strongholds (U.S. Department of the Interior 2015d). The Clearwater River is one of four basins that contain the healthiest and most stable bull trout populations in the recovery unit.

The Clearwater River basin includes four core areas: South Fork Clearwater River, North Fork Clearwater River, Lochsa River, and Selway River. Bull trout are distributed throughout most of the large rivers and associated tributary systems within the Clearwater River core areas and exhibit adfluvial, fluvial, and resident life history patterns.

Bull trout are widely distributed throughout the South Fork Clearwater River. Trend data for the South Fork Clearwater River core area (Meyer et al. 2014) has been previously cited to indicate that bull trout are exhibiting a declining trend in this core area (Meyer et al. 2014, U.S. Department of the Interior 2015a, d). This was an erroneous interpretation of that data and ignored the study author's analysis and discussion of data quality. Screw trap data from the South Fork Clearwater Core Area showed an increasing trend in abundance, while snorkeling data from the same area showed a decreasing trend in abundance. However, the snorkeling data was found by the authors to have a high level of observation error that influenced its reliability, while the screw trap data had zero observation error and therefore a high level of reliability. For these reasons, a more appropriate interpretation of that study is the one made by the study authors that the South Fork Clearwater Core area showed an increasing trend in abundance based on screw trap data (Meyer et al. 2014). Fluvial and resident bull trout are the predominant life history forms known to occur within this core area. Bull trout are currently known to use habitat in five stream complexes within the South Fork Clearwater local populations. These local populations include Red River Complex, Crooked River Complex, Newsome Creek Complex, Tenmile Creek Complex, and Johns Creek Complex.

Bull trout are widely distributed within the North Fork Clearwater River core area, with bull trout redds documented in at least 33 streams associated with the 12 stream complexes since 1994 (Hand et al. 2018). Bull trout are currently known to use habitat in at least 12 streams or stream complex local populations. These local populations include the Kelly Creek Complex, Cayuse Creek Complex, Moose Creek Complex, Upper North Fork Clearwater River Complex, Weitas Creek Complex, Quartz Creek, Skull Creek, Isabella Creek, Little North Fork Clearwater River Complex, Floodwood Creek, Fourth of July Creek, and Fish Lake. Fish Lake, which was thought to support a small adfluvial population (which may actually be a resident population), was formerly a separate core area and is now included within this core area. Based on redd counts as an indicator of abundance, populations in this core area are increasing.(U.S. Department of the Interior 2015d, Meyer et al. 2014, Erhardt and Scarnecchia 2014).

The Salmon River basin includes two core areas within the Nez Perce-Clearwater: Little Lower Salmon River Core Area and the Middle Fork Salmon River–Chamberlain Core Area. Within the Little Lower Salmon River Core Area, bull trout are currently known to use spawning and rearing habitat in three streams or stream complex local populations on the Nez Perce-Clearwater. These local populations include Slate Creek, John Day Creek, and Rapid River. The mainstem Salmon River provides for migration, adult and sub-adult foraging, and rearing and wintering habitat. The Little Salmon River also provides for foraging and adult rearing habitat and connectivity between local populations in the core area. The most recent trend information for this core area showed that the population is stable (Meyer et al. 2014) (U.S. Department of the Interior 2015d).

Within the Middle Fork Salmon River–Chamberlain Core Area, bull trout are currently known to use spawning and rearing habitat in four streams or stream complex local populations on the Nez Perce-Clearwater. These local populations include Bargamin Creek, Wind River, Sheep Creek, and Sabe Creek. The mainstem Middle Fork Salmon River provides for migration, adult and sub-adult foraging, and rearing and wintering habitat. Bull trout spawning and rearing occurs in the upper reaches of the creeks and subadult and adult rearing occurs in the remainder of the drainages. The most recent trend data from Idaho Department of Fish and Game (U.S. Department of the Interior 2015d) indicates that this core area's population is increasing.

Bull trout are currently known to use habitat in 17 streams or stream complexes within the Lochsa River drainage (i.e., local populations).These local populations include Fishing, Legendary Bear, Boulder, Fox, Shotgun, Crooked Fork/Hopeful, Rock, Haskell, Colt Killed (White Sands), Beaver, Storm, Brushy Fork, Spruce, Twin, Walton, and lower Warm Springs Creeks and Fish Lake . Bull trout are currently known to use habitat in at least 10 streams or stream complexes (i.e., local populations) within the Selway River drainage These local populations include Meadow Creek Complex, Moose Creek Complex, Little Clearwater River Complex, Running Creek Complex, White Cap Creek Complex, Bear Creek Complex, Deep Creek Complex, Indian Creek Complex, Magruder Creek, and Upper Selway River Complex (U.S. Department of the Interior 2015d).

There has been some concern about introgression from non-native brook trout (Peterson, Reiman, and Young 2009), but a recent study in the plan area (Voss et al. 2023) found that

"Brook Trout and Bull Trout rarely co-occurred in reaches where they had the geographic and physiological opportunity to do so, and this pattern was consistent across a wide range of abiotic conditions".

This spatial separation may be effective in limiting interactions between them.

The Idaho Department of Fish and Game (IDFG) has completed extensive analysis of bull trout trend data throughout the state. Using models that accounted for the variation in data quality has provided insight into trends statewide and within the national forest. The state's analysis of state space model parameters has indicated that bull trout are stable or increasing in most IDFG surveyed streams on the national forest and determined that most streams are likely at or near carrying capacity for bull trout (Meyer et al. 2014). The lack of strong bull trout population trends on the national forest is consistent with the notion that bull trout populations are stable and are at or near carrying capacity, which is not surprising for a wide-ranging predatory fish that functions at a high trophic level (High et al. 2008) (Meyer et al. 2014).

Designated Critical Habitat: There are 1,680.25 miles of designated critical habitat for bull trout within the boundary of the Nez Perce-Clearwater. The Clearwater River basin contains 1,282.35 miles of critical habitat within five subbasins: the Lochsa River contains 303.14 miles, the Middle-Lower Clearwater contains 22.88 miles, the North Fork Clearwater contains 355.21 miles, the Selway River contains 290.42 miles, and the South Fork Clearwater River contains 310.72 miles. The Salmon River basin contains 397.90 miles of critical habitat within the national forest boundary. The Little-Lower Salmon contains 201.65 miles, and the Middle Salmon River-Chamberlain River contains 196.25 miles.

Critical habitat for bull trout was designated most recently on October 10, 2010 (Federal Register Vol. 75, No. 200). See map in Appendix A. The U.S. Forest Service received a Biological Opinion from the U.S. Fish and Wildlife Service for bull trout rangewide on federal lands in 2018 (U.S. Department of the Interior 2018a).

Snake River Sockeye Salmon (*Oncorhynchus nerka*)

Status and Distribution: Snake River sockeye salmon were listed as an endangered species on November 20, 1991 (Federal Register, Vol. 56, p 58619). A 5-year status review was released in 2016 (National Oceanic and Atmospheric Administration 2016). On the Nez Perce-Clearwater, sockeye salmon are found in the mainstem Salmon River only, which functions as a migratory corridor for this species. No spawning or rearing habitat is located on the Nez Perce-Clearwater. Sockeye salmon are not found in the Clearwater Basin.

Designated Critical Habitat: The mainstem Salmon River, from its headwaters to the confluence with the Snake River, is included as critical habitat for Snake River sockeye salmon. Critical habitat for Snake River sockeye salmon was designated on December 28, 1993 (Federal Register, Vol. 58, No. 247, p 68543), effective on January 27, 1994. Other than the mainstem Salmon River, there is no designated critical habitat for this species on the Nez Perce-Clearwater.

Species of Conservation Concern

Pacific Lamprey (Entosphenus tridentatus)

Status and Distribution: Pacific lamprey are not listed under the Endangered Species Act (ESA) but have been proposed as a Species of Conservation Concern under this Land Management Plan and are a State of Idaho endangered species. They are listed on the state endangered list in part because they have low and declining populations. Pacific lamprey were petitioned for ESA-listing along with three other lamprey species in 2003, but the U.S. Fish and Wildlife Service 90-day determination, released in 2004, was that listing was unwarranted (69 FR 77158). Historically they were widely distributed in the Snake River below Shoshone Falls, and juveniles were commonly seen in Idaho streams in the 1960s; now lamprey are only found in the Salmon and Clearwater drainages and tributaries to the Snake River below Hells Canyon Dam. They are irregularly distributed in the

Clearwater drainage (Cochnauer and Claire 2004, Idaho Department of Fish and Game 2011). These prehistoric fish are anadromous and spend at least a year and half in the ocean as parasites attached to fish and marine mammals. Adults migrate to tributary streams and spawn in the spring and summer, dying soon after spawning. Juveniles burrow in sand and silt and can live in freshwater for up to seven years before migrating to the ocean. Larval lamprey rear in tributary streams with high water quality, large woody riparian vegetation, and overhanging banks, and low velocity areas with fine substrate (Cochnauer and Claire 2004, Idaho Department of Fish and Game 2011). Areas where juvenile lampreys are known to exist include Red River, Newsome Creek, the mainstem South Fork Clearwater River, the mainstem Selway River, the mainstem Salmon River, the mainstem Lochsa River, Crooked Fork Creek, the mainstem Clearwater River, the Potlatch River watershed, and Lolo Creek (Figure 48).

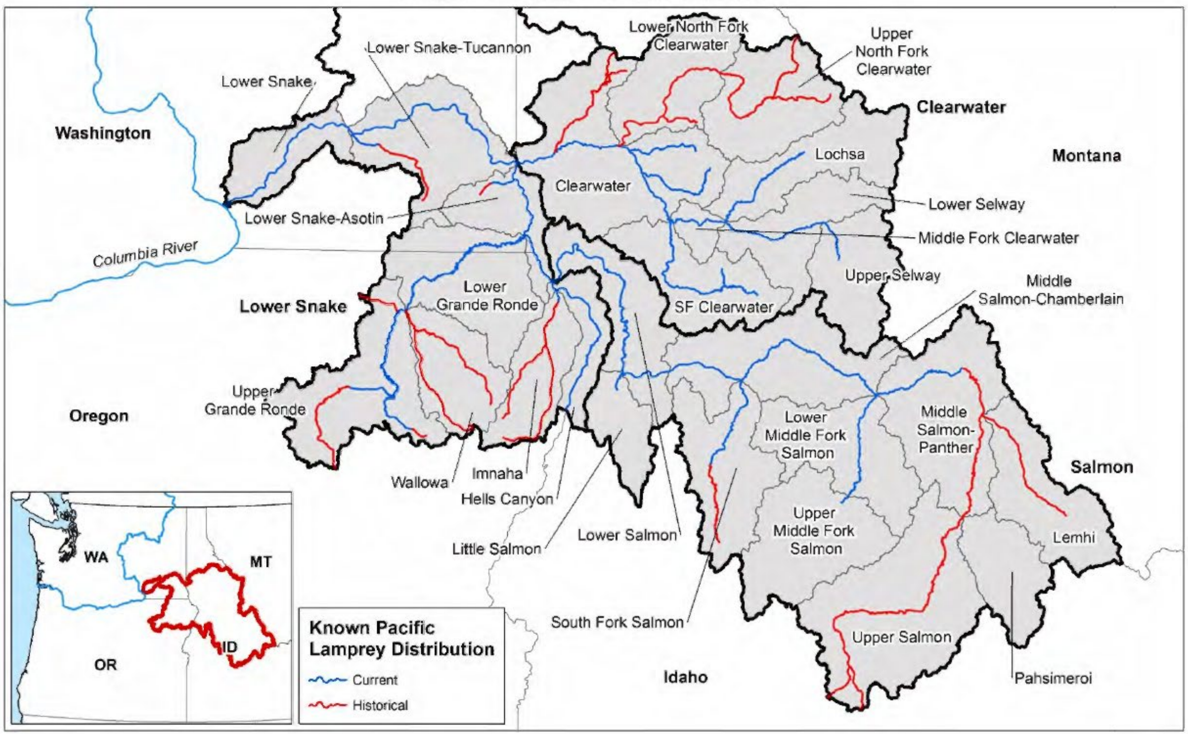

Figure 48. Current Pacific lamprey distribution and location of 16 4th HUCs in the Snake River Regional Management Unit (USFWS Data Clearinghouse 2017) (reproduced from US Department of Interior 2018)

In Idaho, Pacific lamprey are listed as endangered under Idaho Code but not under the federal Endangered Species Act (ESA) (Idaho Department of Fish and Game 2019a). Species listed as threatened and endangered wildlife under Idaho Code have no statutory protection in contrast to the federal ESA. Their classification as threatened or endangered is a policy statement for management and not for legal purposes.

Pacific lamprey are native to Idaho. The Idaho Department of Fish and Game is a signatory to the Conservation Agreement for Pacific lamprey in the states of Alaska, Washington, Oregon, Idaho, and California (Pacific Lamprey Conservation Agreement 2012). The agreement is designed to promote implementation of conservation measures for Pacific lamprey throughout its range. Historic abundance of Pacific lamprey in Idaho is not well documented; however, in recent years, rangewide abundances have been increasing due to improvements in upstream passage at hydropower facilities and translocations by tribal programs in the Snake River basin. The primary management focus in

Idaho will be continued monitoring of habitat occupancy within rivers and streams accessible to anadromous fish and continued cooperation with Tribal entities on translocations programs in Idaho. Towards that end, a collaborative effort between the U.S. Fish and Wildlife Service, the Idaho Department of Fish and Game, and tribes using eDNA sampling was initiated in 2018 that spans the extent of potential Pacific lamprey habitats in Idaho. Information regarding species occurrence from the new eDNA data sets can be used with historical survey information to develop distribution models and better describe status and trends (Idaho Department of Fish and Game 2019a).

The Nez Perce Tribe supplements adult Pacific lamprey that are collected from three lower mainstem Columbia River dams, overwintered at the Nez Perce Tribal Hatchery on the Clearwater River at Cherry Lane, and released into target tributaries in the Snake, Clearwater, and Salmon basins. In 2019, the Nez Perce Tribe expanded their efforts and began releasing adult lamprey into the East Fork of the Potlatch River. These adults were not overwintered but directly released in the fall. Additional summer releases occurred in the Lolo Creek, Orofino Creek, Newsome Creek, and Red River drainages in central Idaho. The Nez Perce Tribe and the Columbia River Inter-Tribal Fish Commission are monitoring movements of the supplemented adults using passive integrated transponder (PIT) tags and detections at PIT tag arrays (Erhardt et al. 2020).

Pacific lamprey is currently designated a sensitive species in the Forest Service Northern Region. This category of designation will be eliminated in the revised plan. The regional forester will create and maintain a new list based on a category known as Species of Conservation Concern (SCC). The Pacific lamprey was recommended to be listed by the regional forester as a SCC on the Nez Perce Clearwater National Forest.

Other Fishes of Interest

This section contains fishes present on the national forest that may be of interest to stakeholders but do not currently have federal status under the Endangered Species Act (ESA) or the revised forest plan. Some of these species are included in management plans by state or tribal authorities, and most are part of important sport fisheries that occur on the national forest. As such, they are economically and culturally important to stakeholders in the plan area and region. To be comprehensive within the plan area, and because they occur within the national forest boundary, status of these species will be discussed, but effects analysis and effects determinations will not be made, with the exception of coho, which lack ESA listing status but retain Essential Fish Habitat under the Magnuson-Steven Act (1976, as amended). However, it is worth noting that since these species of interest are sympatric with fish species that have federal status, they are expected to receive similar benefits from plan components designed to address aquatic habitat and stream function.

Clearwater Spring and Summer Chinook (*Oncorhynchus tshawytscha*)

Status and Distribution: Clearwater spring and summer Chinook are not listed under the ESA, nor are they considered a SCC. They are a hatchery origin stock that is released at several locations within the plan area, and as such are widely distributed throughout the Clearwater Basin, offering regionally renowned sport and tribal fisheries in several areas, including the Lower Clearwater, Middle Clearwater, South Fork Clearwater, North Fork Clearwater (below Dworshak Dam), and the Middle Fork Clearwater.

Spring and summer Chinook salmon in the Clearwater Basin historically were part of two (Wet and Dry Clearwater) out of seven Major Population Groups that are considered extirpated. They are not listed under the Endangered Species Act (ESA) because Lewiston Dam, constructed in the 1920s, had inadequate fish passage and eliminated the native run because very few fish were successful at passing the dam Mathews and Waples 1991 (Waples, Johnson, and Jones 1991, Waples, Jones, et al.

1991). Incidentally, the earliest recorded fish passage records from Lewiston Dam observed only summer-run fish, indicating that the Clearwater run may have been primarily a summer run (Holmes 1961). Following fish passage modifications that were completed around 1940, spring Chinook salmon from out-of-basin stocks were reintroduced by the State of Idaho and U.S. Fish and Wildlife Service, primarily through egg outplants into gravel rearing channels established at state-operated facilities on the Nez Perce-Clearwater. These egg outplants did not result in high numbers of adult returns in the 1950s (mean 35 per year) and began to increase in the early 1960s (mean 52 per year), with more fish returning in the late 1960s and early 1970s (mean 1215 per year) (Lindland 1979). Following removal of the dam in 1973, Chinook salmon reintroduction efforts were expanded by the State of Idaho with smolt releases in the 1970s and joined by the U.S. Fish and Wildlife Service with smolt releases in the 1980s. These reintroduction efforts used fish from out-of-basin sources, primarily Rapid River (state programs) and the lower Columbia River (federal programs), and a hatchery-origin run was established throughout most of their historic range in the Clearwater Basin, with the primary objective of providing sport and tribal harvest opportunities. Spring and summer Chinook salmon continue to be released into the Clearwater basin through an extensive hatchery program primarily coordinated through the Lower Snake Compensation Plan, with the goal of mitigating for lost harvest opportunities due to the federal Lower Snake River Dams. Annual smolt or parr release targets for these hatcheries are currently 6,874,000 fish released into the Clearwater basin (Leth and Noyes 2022). Adult hatchery fish that escape harvest and spawn in the Clearwater River have created a small, naturalized component of this stock that is not considered distinct (from an ESA perspective) from the hatchery produced component and now occupy rivers and streams throughout the Clearwater Basin, as shown in the distribution maps in Appendix A. Most hatchery fish released in this basin receive an adipose fin clip to distinguish them from naturally produced fish. Intentional releases of unclipped hatchery fish occur in this basin, with rates varying by year, but averaging approximately 10 percent. For example, in 2021 unclipped hatchery releases totaled 10.7 percent of total spring and summer Chinook releases in the Clearwater basin (2021 Clearwater AOP). In 2021, estimated returns of unclipped adult Chinook to this basin were also approximately 10 percent (2021 Clearwater AOP), and although some of these fish are presumably naturally produced, this proportion includes unclipped hatchery fish. Spring and summer Chinook salmon occupy rivers and major tributaries throughout the Lochsa, Selway, Middle Fork, and South Fork Clearwater rivers and many of their tributaries.

Foreign populations of anadromous salmonids frequently perform poorly compared to stocks within their original range, presumably due to lack of local adaptation (Taylor EB 1991, Waples 1991, Fraser et al. 2011, McConnell et al. 2018). Increased hatchery supplementation in the Clearwater has failed to produce lasting increases in abundance or productivity (Vendetti et al 2018). Clearwater spring and summer Chinook have routinely exhibited lower smolt-to-adult return rates (approximately half) compared to South Fork Salmon River fish, even though South Fork Salmon River fish were one of the primary original broodstock sources used by Idaho Department of Fish and Game facilities to establish Clearwater stocks (Leth and Noyes 2022). Similar results are also reported in wild populations, for example, Peterson et al. (2014) reported that lack of local adaptation in a wild sockeye salmon stock resulted in half as many offspring. These results underscore the importance of local adaptation in cultivating population resilience in recovery of salmonid populations, which is likely to be even more important in the face of climate change. The uncertainty of the original run timing (likely primarily summer run), as well as the lack of local adaptation in Clearwater spring/summer Chinook are unlikely to be advantageous in the populations' probability of resilience in the future as they experience the effects of climate change. This is evident in predictions of adult pre-spawn mortality based on Northwest temperature predictions through 2040 found in Bowerman et al. (2021), who, although they erroneously included Clearwater fish with the Snake River Evolutionary Significant Unit (ESU), predicted that hatchery fish, and Clearwater fish would be likely to exhibit higher temp related pre-spawn mortality than Endangered Species Act (ESA) listed wild fish

Although Clearwater spring and summer Chinook were not included in the Snake River ESU of ESA listed fish (Good et al. 2005), The Interior Columbia Technical Recovery Team does continue to monitor hatchery populations within the Wet and Dry Clearwater major population groups (MPGs)(which are both extirpated MPGs) (Figure 49), as well as the other extirpated MPGs, in order to provide ongoing assessment of the conservation value that these populations may have in the future (U.S. Department of Commerce 2007). In the latest 5-year review for the Endangered Species Act listed stock (National Oceanic and Atmospheric Administration 2022), National Oceanic and Atmospheric Administration Fisheries detailed the current relationship that Clearwater spring and summer Chinook have with the ESU:

"Four non-ESA-listed hatchery programs operate in the Clearwater River basin: Kooskia spring Chinook, Clearwater Fish Hatchery spring/summer Chinook salmon, Nez Perce Tribal Hatchery spring/summer Chinook salmon, and Dworshak spring Chinook salmon programs. Chinook salmon in the Clearwater River are not part of the listed Snake River (SR) spring/summer Chinook salmon ESU, and critical habitat for the ESU was not designated in the Clearwater River basin. The hatcheries in the Clearwater basin are operated as segregated programs and focus on keeping hatchery fish separate from natural-origin populations. NMFS completed a consultation on these programs in 2017 and determined that the programs are not likely to appreciably reduce the likelihood of survival and recovery of the (Snake River) spring/summer Chinook salmon ESU (NMFS 2017d). These hatchery programs have implemented new strategies to limit straying of program fish into areas where ESA-listed fish are present (NMFS 2017d). Straying effects and population-level pHOS values of all programs do not constitute a serious threat to the (Snake River) spring/summer Chinook salmon ESU. They are considered negligible since all of the population level pHOS values from the proposed programs are below 0.05."

To provide more fisheries in the Clearwater basin, the State of Idaho has operated a hatchery summer Chinook program since 2009, utilizing hatchery broodstock from the South Fork Salmon River. Smolts were originally released in 2011 from Crooked River, but poor returns prompted a move in 2014 to release fish from the Powell satellite facility on the upper Lochsa (IDFG et al. 2022).

Clearwater spring and summer Chinook salmon are no longer present in the North Fork Clearwater River above Dworshak Dam, as this population was already extirpated before construction of Dworshak Dam in the late 1960s and early 1970s. Dworshak dam was completed in 1973. Although they were previously a sensitive species under the 1987 plan, spring and summer Chinook salmon in the Clearwater basin are a not a Species of Conservation Concern, primarily because the original stock was extirpated, and the reintroductions utilized out-of-basin fish that do not currently meet the criteria of being native (Matthews and Waples 1991, Waples 1991) to the plan area. The decision to consider them non-native provides consistency between federal agencies, in this case between Forest Service and National Oceanic and Atmospheric Administration Fisheries.

The lack of local adaptation, in combination with continued use of out-of-basin eggs to supplement shortages, and low observed percentage of natural origin broodstock (pNOB) values within the Clearwater Basin (Horn et al. 2023) suggest that this stock is likely to remain dependent on hatchery supplementation. As there are federal hatchery programs (Lower Snake Compensation Plan and Mitchell Act) in place to provide funding for that supplementation, it is expected that this stock will persist over the life of the plan. The importance of the sport and tribal fisheries that are provided by this stock to the region cannot be understated. They are vastly important culturally and economically to the area. Although these fish benefit from forestwide plan components designed to protect aquatic habitat and fisheries, they are also expected benefit from a "fine filter" plan component (FW-GL-WLMU-02) that is designed to promote collaboration with partners for conservation of this population, which provides culturally and economically important fisheries in the Clearwater basin.

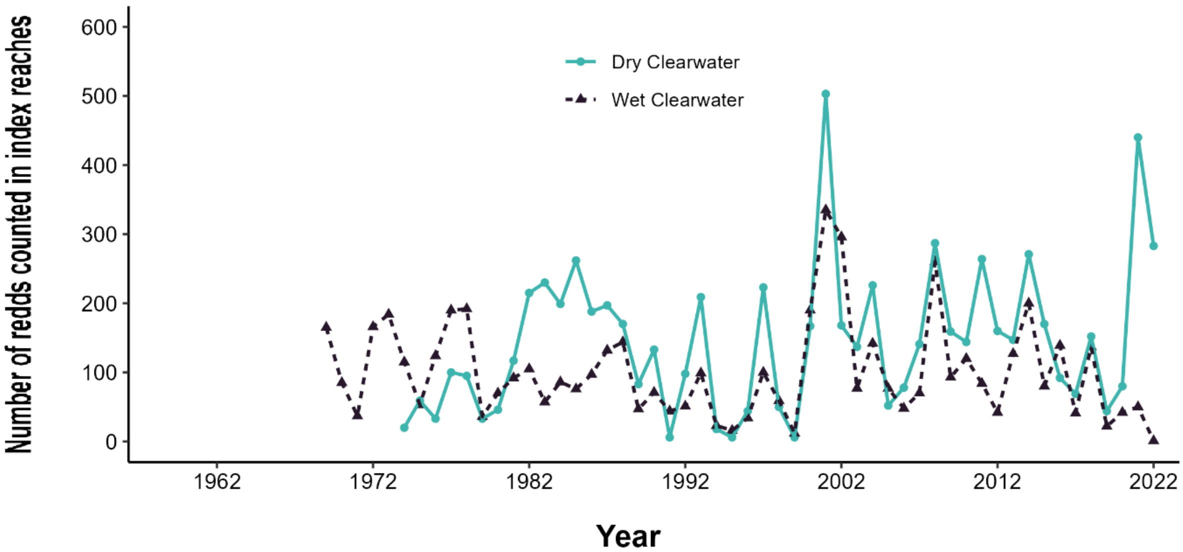

Figure 49. Spring and summer Chinook salmon index redd count trends in the Clearwater River Idaho, by major population group (in this instance these are considered extirpated major population groups) from 1966 to 2022. (Data from IDFG).

Westslope Cutthroat Trout (*Oncorhynchus clarki lewisi*)

Status and Distribution: Westslope cutthroat trout is not listed under the Endangered Species Act nor is it proposed as a Species of Conservation Concern. It is the Idaho state fish. The species is widely distributed across the Nez Perce-Clearwater. It provides a regionally renowned sport fishery in several areas, including the Lochsa, North Fork Clearwater, and Selway rivers and the Kelly Creek tributary to the North Fork Clearwater River.

Kennedy and Meyer (2015) found that westslope cutthroat trout are generally stable or increasing in abundance across much of Idaho. In the Clearwater River subbasin, the population growth was positive or stable. No samples showed statistically negative population growth. Data was collected through screw traps, snorkeling, and angling in the Lochsa River, including Colt Killed Creek and Crooked Fork Creek; the South Fork Clearwater River, including Red River and Crooked River; and the Selway River, including tributaries. Mallet and Thurow (2022) recently characterized the successful westslope cutthroat trout recovery in Idaho as an example and pattern of conservation success for others to follow. There has been concern in the past about the potential for non-native rainbow trout introgression with westslope cutthroat trout on the North Fork Clearwater River (Weigel et al. 2003) and competition with non-native brook trout, however, non-native rainbow trout stocked above Dworshak by IDFG have been sterile triploids since the 1990's, and non-triploid brook trout are no longer stocked on the forest. Where they do overlap, modelling suggests that warming temperatures expected to occur due to climate change may be beneficial to cutthroat and detrimental to brook trout (Wenger et al. 2011).

Westslope cutthroat trout were designated as a sensitive species on the Nez Perce and Clearwater national Forests in 2011 but will not be included on the SCC list in part because of high abundance and a revision in the State of Idaho NatureServe ranking to S4 – Apparently Secure. They were also a management indicator species under both the 1987 Nez Perce and Clearwater Forest Plans. The SCC category under the new plan has different criteria from the old sensitive species list (77 FR 21162, April 9, 2012). Westslope cutthroat trout will not be included in the SCC species list for the Nez Perce-Clearwater National Forest under the revised plan, as they do not meet the criteria.

Sculpin (*Cottus* spp.)

Several species of sculpin have been described in the Clearwater basin, including Mottled (*C. bairdi*), Torrent (*C. rhotheus*), Paiute (*C. beldingi*), which were reported to be distributed primarily in lower and middle elevations, and Shorthead (*C. confusus*), which were reported to be distributed higher in the Clearwater watershed ((Maughan 1978), (Maughan and Saul 1979). Hubbs and Schultz reported a distinct sculpin in 1932 (*C. tubulatus*) in what was presumably the Potlatch River from the narrative description (most likely misidentified in publication as "a tributary to the North Fork Clearwater" by the study authors, but this error was corrected by Maughan in 1974)(Young et al. 2022). Young et al. (2013), in examining the genetic structure of various populations of sculpins, noted that "sculpins in the Clearwater River may warrant additional taxonomic attention due to indication of high intraspecific divergence." There are likely similar assemblages of sculpin in the Salmon River, however, none have been described in the literature. It is worth noting here that sculpin species are notoriously difficult to differentiate, and genetic techniques will likely improve sculpin taxonomy in the future, but sculpin assemblages on the Nez Perce-Clearwater are widely distributed and important to the ecology of streams on the national forest.

Coho Salmon (Oncorhynchus kisutch)

Coho salmon were historically native to the Clearwater basin but were extirpated. Reintroduction efforts by the State of Idaho began in the 1960s but were abandoned after years of poor success, and coho were declared extirpated in 1985 (Galbreath et al. 2014). In 1994, as part of the Snake River Basin Adjudication, the Nez Perce Tribe began reintroduction efforts in the Clearwater River using surplus eggs from Lower Columbia River hatchery programs. Tribal reintroduction efforts in the basin have been very successful, with a new reintroduction program expanding into the Lostine River in the Wallowa watershed in the Grande Ronde basin (adjacent to the plan area) in Washington in 2018. With the addition of the Wallowa program the Tribe release goals are over 1.2 million smolts into watersheds above Lower Granite Dam. Figure 50 shows adult coho returns by year to Lower Granite Dam. Except for fish destined for the Wallowa basin, these fish originated from, and will return to, streams and hatcheries within the plan area. Because the original stock was extirpated, and subsequently re-introductions used out-of-basin stocks, coho within the plan area are not eligible for Endangered Species Act listing. However, under the Magnuson-Stevens Act, their historic range in the Clearwater basin is still designated as essential fish habitat (EFH) for coho, primarily because it is done for an aggregate of all United States stocks, and because EFH is determined at the subbasin (HUC 8) scale. The plan component FW-GL-WLMU-02 is designed to promote collaboration and conservation of this species, which provides culturally and economically important fisheries in the Clearwater basin.

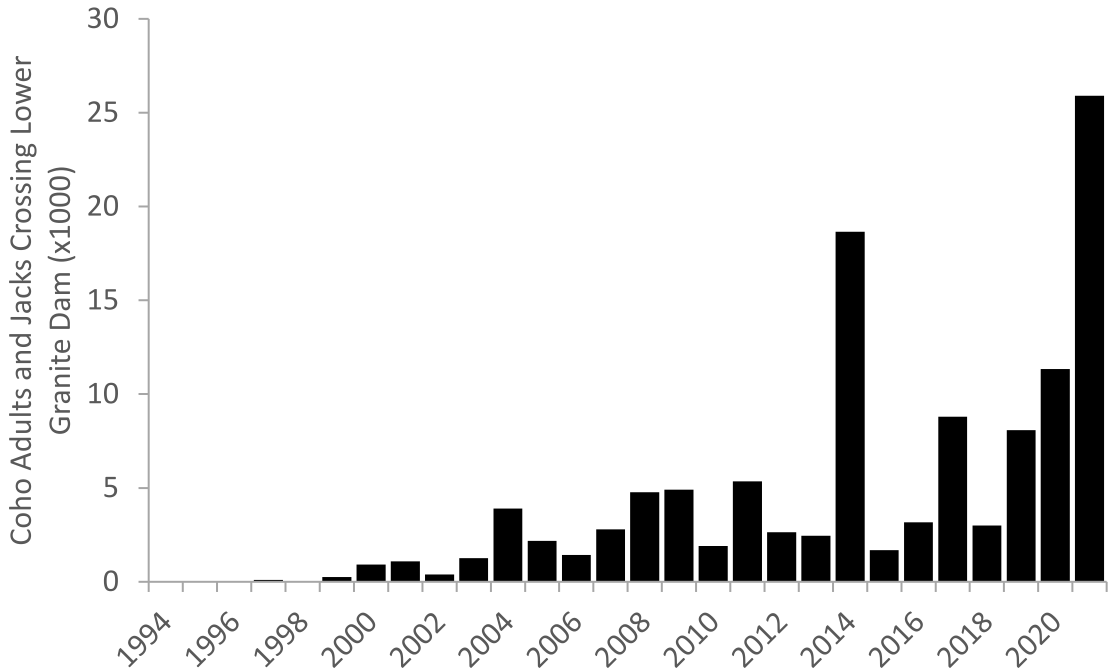

Figure 50. Total adult and jack coho returns to Lower Granite Dam, Washington by return year from 1994 to 2021. Data from the fish passage center (FPC.org).

Non-Native Fish Species

Most waters on the Nez Perce-Clearwater have a history of fish stocking, and populations of non-native gamefish have become established in many areas. Most notable include brook trout (*Salvelinus fontinalis*) which are widely distributed and abundant in many streams and mountain lakes, and kokanee (*Oncorhynchus nerka*), which is the landlocked form of sockeye salmon. Kokanee were introduced into Dworshak Reservoir and are well established above Dworshak dam. They spawn in the Upper North Fork Clearwater River and tributaries. Smallmouth bass (*Micropterus dolomieui*) are present in the North Fork Clearwater, Mainstem Clearwater (primarily above Orofino as hypolimnetic releases from Dworshak dam limit bass abundance between Orofino and Lewiston), Middle Fork Clearwater, South Fork Clearwater, and Salmon Rivers, as well as Dworshak Reservoir. All these species provide economically important sport fisheries on the Nez Perce-Clearwater.

Mollusks

Pristine Pyrg (*Pristinicola hemphilli*)

Status and Distribution: This species is a rare aquatic snail known to occupy a narrow range of habitats associated with springs and seeps. The species has a broad distribution in the lower Columbia and Snake River basin in Washington, Idaho, California, and Oregon (Hershler et al. 1994). Colonies are scattered through the Columbia and Snake River basins into western Idaho, and it can also be found in interior Oregon in the Deschutes, Umatilla, and John Day River basins and in the Rogue, Umpqua, and Smith River basins in southern Oregon and Del Norte counties in northern California. It once occurred in Montana, but recent surveys suggest it is now extirpated from this region (Richards et al. 2005). Throughout its range, it was assigned a “vulnerable” classification in a conservation assessment by (Johnson et al. 2013). In Idaho, it has an S3 NatureServe rank, meaning that it is rare or uncommon but not imperiled.

This species is typically found inhabiting small springs, seeps, occasionally larger springs, spring outflow channels, and spring influenced stream reaches (Stagliano et al. 2007). The springs in which it is found are usually in semi-arid areas where sagebrush is dominant on a basalt substrate, though it has also been found in areas that are dominated by Douglas-fir (Frest and Johannes 1995).

On the Nez Perce-Clearwater, discrete and extremely small populations are suspected to exist in the Lower Salmon subbasin. Surveys are needed to establish specific distribution.

Western Pearlshell Mussel (*Margaritifera falcata*)
Status and Distribution: The Western pearlshell mussel is a filter feeding mussel that is widely distributed throughout the Pacific Northwest. The larval form is an obligate parasite that requires a specific fish host, usually a salmonid (*Oncorhynchus* sp). They occur in sand, gravel, cobble, and boulders in a variety of stream habitats ranging from low to moderate gradient streams up to larger rivers (Stagliano et al. 2007). Both biotic factors such as host species abundance, and abiotic factors such as water quality, substrate size, and stream geomorphology influence abundance and distribution. In a well-known study in the Salmon River, Vannote and Minshall (1982) noted large populations and characterized geofluvial processes affecting distribution and abundance in larger rivers.

"Mussels attain maximum density and age in river reaches where large boulders structurally stabilize cobbles and interstitial gravels. Boulders tend to prevent significant bed scour during major floods, and these boulder-sheltered mussel beds, although rare, may be critical for population recruitment elsewhere within the river, especially after periodic flood scour of less protected mussel habitat" (Vannote and Minshall 1982).

Western pearlshell mussels have been the subject of concern in several western states, as researchers have observed large-scale die off events in some rivers and streams. The cause of these die offs is unknown, and current research is ongoing to determine the responsible pathology. Several hypotheses have been advanced regarding potential causes, including bacteria (Thomas 2008), viruses (Richard et al. 2023), water temperature (Stagliano 2023), toxic algae (Thomas 2008), and contaminants (Helmstetler er al. 2008), but a common etiology has not yet been reported.

This species is widely distributed and has been reported to be abundant in a variety of habitat types, including large river (up to 192 mussels/m2 in boulder reaches in a 40 km section of the mainstem Salmon River (Vannote and Minshall 1982), and small streams (up to 47,468 mussels/100m in Lolo Creek (Erhardt et al.) across the Nez Perce-Clearwater (Figure 51). Large populations are known to exist in the mainstem Selway River, mainstem Salmon River, mainstem Clearwater River, South Fork Clearwater River, Lolo Creek, Crooked River, and American River, Ruby Creek, Musselshell Creek, Jim Brown Creek, Eldorodo Creek, and a small population is known to exist in the Palouse River Drainage (Meadow Creek) on private land within the administrative boundaries of the national forest. Surveys of these populations indicate multiple size classes are present (Vannote and Minshall 1982, USDA 2008, USDA 2009, Erhardt et al. 2022), and existing data suggest populations are stable. The U.S. Fish and Wildlife Service is currently working on establishing and monitoring long-term index-of-abundance sites on several streams on the national forest. The State of Idaho records Western pearlshell mussel observations through their Idaho Species Diversity Database, and to date has reported 642 observations of Western pearlshell mussels (most reports are of multiple individuals) in Idaho. Western pearlshell mussels have been designated as a Species of Greatest Conservation Need under Idaho's State Wildlife Action Plan.

The species is designated a sensitive species in the Forest Service Northern Region. This category of designation will be changed in the revised plan. The sensitive species category will be eliminated under the new plan, and a new category, Species of Conservation Concern (SCC), will be established. Criteria for SCC is outlined in the 2012 Planning Rule. Western pearlshell mussel is not listed as a SCC under the revised plan, however it will be a focal species under the monitoring plan.

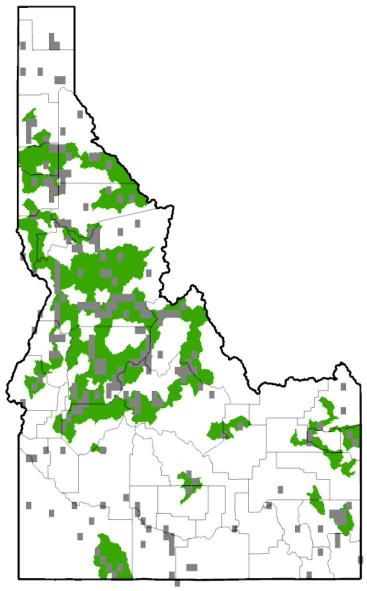

Figure 51. Western pearlshell mussel observations in Idaho. Gray represents observation locations, and green is the modeled range. (Data from Idaho Species Diversity Database accessed 1/10/2023).

Western Ridged Mussel (*Gonidea angulata*)

Status and Distribution: Western ridged mussel is a large, native mussel that occurs primarily in larger mainstem rivers in the plan area (Figure 52). The larval form is an obligate parasite that requires a specific fish host, usually sculpin (*Cottus* spp.). Records of Western ridged mussels on the national forest are sporadic and so far limited to large mainstem rivers such as the mainstem Clearwater and Salmon Rivers. They have been reported to occur near 6 Mile Creek on the mainstem of the Clearwater by the U.S. Fish and Wildlife Service (John Earhardt, USFWS, personal communication), and at several locations on the mainstem Salmon River by Vannote and Minshall (1982), who reported densities up to 183 mussels per square meter in sand and gravel habitat types, and predicted that this species would probably replace pearlshell in more aggraded habitats in that system. The State of Idaho records western ridged mussel observations through their Idaho Species Diversity Database, and to date has 271 reported observations of Western ridged mussels (in most cases reports are of multiple individuals) in Idaho. The U.S. Fish and Wildlife Service was petitioned by the Xerces Society to list the mussel under the Endangered Species Act (ESA) in 2020, and in June 2021 the service published its 90-day finding in the federal register stating that the mussel may warrant listing, and that they would undertake a 12-month status review. The Western ridged mussel was not selected as a SCC species on the national forest because the most current information on abundance and trends indicates stable populations. Past records indicate that this mussel was abundant in larger mainstem rivers on the national forest. In 2021 and 2022, Idaho Department of Fish and Game conducted statewide surveys for Western ridged mussels in order to provide information for the U.S. Fish and Wildlife Service species status assessment. They found them to be widely distributed throughout the state, and found no evidence of mass die-offs like those that have been reported in other West Coast states that prompted the current ESA-listing petition, and in fact, Idaho Department of Fish and Game observed one exceptionally large population in the Salmon River (Joel Sauder, Idaho Department of Fish and Game, personal communication). Idaho Department of Fish and Game is continuing monitoring of Western ridged mussels throughout the state and on the national forest.

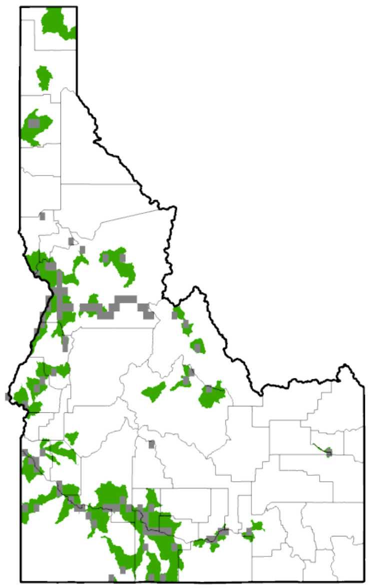

Figure 52. Western ridged mussel observations in Idaho. Gray represents observation locations, and green is the modeled range. (Data from Idaho Species Diversity Database accessed 1/10/2023).

Ashy Pebblesnail (*Fluminicola fuscus*)

This species is known to occur on the national forest and is widely distributed throughout Idaho. As such, it has a S3 state NatureServe ranking (vulnerable), meaning that it is uncommon but regularly occurring and not imperiled. It was evaluated for inclusion on the Species of Conservation Concern (SCC) list but was omitted because it did not meet the criteria.

Shortface Lanx (*Fisherola nuttalli*)

This species is known to occur on the national forest and is widely distributed throughout Idaho. As such, it has a S3 state ranking (vulnerable), meaning that it is uncommon but regularly occurring and not imperiled. It was evaluated for inclusion on the SCC list but was omitted because it did not meet the criteria.

Green River Pebblesnail (*Fluminicola coloradensis*)

This species is known to occur on the national forest and is widely distributed throughout Idaho. As such, it has a S3 state ranking (vulnerable), meaning that it is uncommon but regularly occurring and not imperiled. It was evaluated for inclusion on the SCC list but was omitted because it did not meet the criteria.

Great Basin Ram's Horn (*Helisoma newberryi*)

This species is known to occur in Idaho (in Bear Lake) but is not known to occur in the plan area. There was one reported observation of this species on the South Fork Clearwater River in 1940, however, it was initially or subsequently identified as a different species (*Carinifer newberryi*). Other than that single report, it has not been reported to occur on the national forest. As such, it was not included on the SCC list.

Rotund Physa (*Physella columbiana*)

This species was described in Idaho in the 1800s and is thought to be extirpated from Oregon and British Columbia but has not been observed on the Nez Perce-Clearwater since 1983. The 1983 observation was of very low locational precision and could reflect an observation outside of the plan area. It is known to occur in the State of Idaho, but not in the plan area, and was omitted from the Species of Conservation Concern (SCC) list.

Pondsnail Group (*Ladislavella* spp.)

This species group consists of eight Ladislavella species: *Ladislavella apicina*, *L. caperata*, *L. elodes*, *L. emarginata*, *L. hinkleyi*, *L. idahoensis*, *L. traski*, and *L. utahensis*. These species are all cold water stenotherms found in cold streams with coarse substrates. All of these species have no state NatureServe ranking and are not known to occur on the national forest. As such, they were not included on the SCC list.

Other Native Aquatic Species on the Nez Perce-Clearwater

There are many additional native aquatic invertebrates, macroinvertebrates, amphibians, and fish on the Nez Perce-Clearwater other than those described above, some of which have some sort of past or existing management status or emphasis. They will not all be discussed in detail but are listed here: *Acrocheilus alutaceus* (chiselmouth), *Ptychocheilus oregonensis* (northern pikeminnow), *Rhinichthys cataractae* (longnose dace), *Rhinichthys osculus* (speckled dace), *Richardsonius balteatus* (redside shiner), *Percopsis transmontana* (sand roller), *Catostomus macrocheilus* (largescale sucker), *Catostomus columbianus* (bridgelip sucker), *Catostomus platyrhynchus* (mountain sucker).

Mountain whitefish (*Prosopium williamsoni*) are widely distributed in rivers and streams on the Nez Perce-Clearwater.

Aquatic Insects

There are no Endangered Species Act (ESA) listed aquatic insects on the national forest, nor are there any aquatic insects that meet the criteria for Species of Conservation Concern (SCC). However, the regional forester maintains a list of sensitive species (SS) for each national forest in the region as required by the 1982 Planning Rule. An update of that list took place concurrently to the writing of the Final Environmental Impact Statement. The Nez Perce-Clearwater reviewed status and distribution information of aquatic species that are listed on the State of Idaho's State Wildlife Action Plan and submitted recommendations to the regional office for inclusion on the regional sensitive species list. Although the sensitive species list will be eliminated under the new plan, the SS list is still updated and maintained in the interim, until the record of decision for the new plan is released. The species that are on the SS list were also considered for inclusion on the new SCC list based on the new criteria. The national forest reviewed and submitted the SCC list recommendations for several aquatic insects including a click beetle (*Beckerus barri*); a skiff beetle (*Hydroscapha redfordi*); several mayflies (*Parameletus columbiae*, *Paraleptophlebia traverae*); Autumn Springfly (*Pictetiella expansa*); Lolo Mayfly (*Caurinella idahoensis*); several caddisflies, including Northern Rocky Mtns. Refugium Caddisfly (*Sericostriata surdickae*) and several without common names (*Georeeilla baumanni*, *Manophylax annulatus*, *Eocosmoecus schmidi*); Paiute Dancer (*Argia alberta*); Idaho Snowfly (*Capnia zukeli*); Strait Snowfly (*Capnia lineata*); Cascades Needlfly (*Megaleuctra kincaidi*); Giant Needlefly (*Megaleuctra stigmata*); Idaho Forestfly (*Soyedina potteri*); Umatilla Willowfly (*Taenionema umatilla*); and Cordilleran Forestfly (*Zapada cordillera*). After regional office review, only two species of aquatic insects were included on the draft SS (as required under the 1982 Planning Rule) list as "suspected" or "known distribution" on the national forest: the Northern Rocky Mtns. Refugium Caddisfly and the Lolo Mayfly. Species that were excluded from the SCC or SS list usually did not have any recent information on abundance and distribution (as required by the planning rule criteria) and had not been observed for decades. For example, *P. columbiae* has not been observed on the national forest since 1965, *P. traverae* has not been observed since the 1930s, and *C. zukeli* and *C. lineata* have not been observed in Idaho since the 1980s (Idaho Department of Fish and Game State Wildlife Action Plan). Both *Capnia* species were petitioned for Endangered Species Act listing by the Xerces Society in 2010, and the U.S. Fish and Wildlife Service found the petition to be unwarranted in 2011 (76 FR 46238). None of the aquatic insect species evaluated for the Species of Conservation Concern (SCC) list were found to meet the criteria for inclusion on that list. A fuller description of the SCC process can be found within the "Rationale (species evaluations) used to select animal and plant species as SCC for NPC draft plan and draft environmental impact statement." None of the aquatic insects that were on the SS list were included on the SCC list. Documentation and rationale for SCC determinations can be found on the Northern Region's Species of Conservation Concern website.[18]

Environmental Consequences

Introduction

To provide context for the discussion of effects for each aquatics resource area in this section, a summary of the history of environmental effects and regulations pertaining to the plan area, as well as best available science related to fisheries and aquatic ecosystems, primarily riparian areas, is provided below. Sections also discuss situations where land allocations or suitability decisions could create varying effects between alternatives, as well as how implementation would differ under different alternatives.

In response to studies in the 1960s and 1970s that documented the harmful effects of timber harvest methods and road building on streams, state and federal agencies began passing a series of management requirements for activities on state and federal lands near streams. These are referred to as "best management practices." Everest and Reeves (2007) disclosed the following regarding the development of best management practices for the Pacific Northwest: "The [best management practices] were developed through the normative process that weighed, evaluated, and incorporated many types of information. The best available scientific information for protection of riparian and aquatic habitats was not always incorporated into forest practice rules." This cycle of not including best available science was repeated several times over the decades, even as successive monitoring efforts continued to document degraded stream conditions (Reeves, Olson, et al. 2016).

A crisis point was reached in the early 1990s in the western United States when several stocks of salmon and trout were reaching critically low numbers (Nehlsen et al. 1991) and ultimately were listed as threatened or endangered under the Endangered Species Act. By the mid-1990s, the Forest Service and Bureau of Land Management had completed three broad-reaching documents—The Northwest Forest Plan (U.S. Department of Agriculture 1994), Decision Notice/Decision Record for Interim Strategies for Managing Anadromous Fish-producing Watersheds in Eastern Oregon, and Washington, Idaho and Portions of California (PACFISH) (U.S. Department of Agriculture 1995c), and Inland Native Fish Strategy Environmental Assessment Decision Notice and Finding of No Significant Impact (INFISH) (U.S. Department of Agriculture 1995c)—hereafter referred to collectively as "the strategies," that amended forest plans across much of the public lands in the West to improve their conservation function. The Northwest Forest Plan and PACFISH (U.S. Department of Agriculture and U.S. Department of the Interior 1995a) addressed the protection of migratory

[18] http://bit.ly/NorthernRegion-SCC

salmon and steelhead; INFISH addressed the protection of habitat and populations of resident native fish outside of anadromous fish habitat.

These strategies departed significantly from past management philosophy and established more stringent requirements to protect species' habitat. One feature of the new strategies was the extension of the distance from the stream to the boundary of riparian management zones, referred to as riparian reserves in the Northwest Forest Plan and riparian habitat conservation areas in PACFISH and INFISH, compared to previous direction, to better protect ecological processes next to streams. Also, the precautionary principle was invoked. Reeves et al. (2016) described this principle as, "Forest managers who wanted to alter the comprehensive default prescriptions for riparian management under the Northwest Forest Plan (NWFP) in order to pursue other management goals were required to demonstrate through watershed analysis that changes would not compromise established riparian-management goals." Not only did the burden of proof shift, but these new strategies also required managers to consider ecological processes at the watershed scale. The components used in the Northwest Forest Plan, including the concept of the precautionary principle, were included in PACFISH and INFISH.

Riparian management has remained controversial, in part because of competing values and uses (Lee et al. 2004). Strategies employed by the Northwest Forest Plan, PACFISH, and INFISH appear to have been successful at halting the loss of old growth due to timber harvest within riparian areas and at preventing damage to aquatic systems in the Pacific Northwest (Thomas et al. 2006) and the intermountain region. However, some suggest a protection mindset emerged that has prevented management within riparian areas that would be desirable to sustain and promote ecological processes beneficial to aquatic or terrestrial ecosystems. Warren et al. (2013) found that reaches with complex old-growth riparian forests had frequent canopy gaps, which lead to greater stream light availability compared to adjacent reaches with simpler second-growth riparian forests. Light availability strongly influences stream primary production, water temperatures, and resource availability at the base of stream food webs.

Speaking on the need to restore ecological conditions and make good on social, economic, and ecological commitments in the Northwest Forest Plan, Thomas et al. (2006) wrote, "Minimization of short-term risks (the modus operandi of regulatory agencies and the federal courts) has a price tag, and a very big one, related to significantly increased longer-term risks of failure to meet objectives over very long time frames. Unless the federal agencies consider the peril of inaction equal to the peril of action, the goals of the NWFP [Northwest Forest Plan] will not be reached." Richardson et al. (2012) wrote: "In an increasingly complicated management arena, the challenge will be to find alternatives to fixed width buffers that meet the multiple objectives of providing clean water (minimizing nutrient and sediment inputs), aquatic habitat, habitat for riparian species, connectivity across landscapes, and related responses." Riparian zones and ecological functions regarding the widths of management areas next to streams, the interim minimum 300 feet distances listed in INFISH for fish-bearing streams and 150 feet in perennial streams, arguably remain the most controversial components of the existing strategies. Numerous studies have been completed since the strategies were first published that investigate how management affects the different ecological processes that are a function of riparian management zones. The ecological processes that function within riparian zones are first discussed individually below and then in combination, as they affect both aquatic and riparian conditions and biota.

Among the more commonly studied management concerns as they relate to ecological processes near streams are the effects of nearby timber harvest on stream temperature. Initial studies completed by

Chen et al. (1993) and the Forest Service's Ecosystem Management Assessment Team (1993) found that streamside buffers of over 400 feet were needed to protect ecological processes such as wind speed and humidity near streams, which at the time were thought to be able to increase stream temperature. This finding contributed to the recommendation for two site potential tree height buffer areas, equaling approximately 300 feet, applied to riparian reserve and riparian habitat conservation area widths in the existing strategies (Everest and Reeves 2007, Reeves, Pickard, and Johnson 2016).

Several studies have been conducted around the width of riparian buffers as it relates to stream temperature, large woody debris in streams and within riparian zones, and sediment filtering to streams. A study conducted in northern Idaho by Gravelle and Link (2007) found that when 50 percent of riparian canopy cover was harvested in the first-order reaches, temperature increased by up to 38.5°F in the directly impacted nonfish-bearing reaches but there was no significant increase in water temperature maxima at the downstream fish-bearing sites. Stream heating depends on multiple environmental variables: net solar and thermal radiation and the degree of shading by riparian vegetation, local air temperature, wind velocity, relative humidity, groundwater inflow, and amount of hyporheic flow. Groundwater can play an important role in maintaining relatively low temperatures in small streams. Timber harvest affects water temperature in streams in two ways: removal of canopy cover that increases incoming solar but reduces incoming thermal radiation and modification of hydrologic processes that regulate the timing and amount of streamflow. Although incoming solar radiation is thought to be one of the most influential factors, investigations of the cumulative effects of largescale timber harvest found that it is a complex set of factors, rather than a single factor, such as shade or air temperature, that governs stream temperature dynamics.

Additional studies have occurred throughout the Pacific Northwest. One study that modeled the effects of riparian reserves on stream temperature in Washington found that the first 33 feet were the most important in protecting stream temperature and that buffers greater than 100 feet did not appreciably lower stream temperatures (Sridhar et al. 2004). A study on headwater stream microclimate by Anderson et al. (2007) found that the first 30 feet had the most effect on microclimate above the stream and that temperatures in the streambed increased only when streamside vegetation closer than 50 feet to the edge of the stream was removed (Anderson and Poage 2014). A study by Sugden et al. (2019) in western Montana found no significant effect to water temperature or fish populations from timber harvest when streamside management zones of 50 to 100 feet exclusion areas were retained. A review of studies by (Moore et al. 2005) suggested that a riparian reserve that was the width of one tree height was likely large enough to protect the ecological processes that control stream temperature. Recently, many researchers have suggested that a 100 foot buffer next to fish-bearing and perennial streams is generally likely to be sufficient to protect against stream temperature increase (Anderson and Poage 2014, Reeves, Pickard, and Johnson 2016, Sweeney and Newbold 2014). Even so, consideration of context and geography is also appropriate. In a discussion of fixed-width riparian buffers, Richardson et al. (2012) acknowledged that although these types of protections are administratively simple to implement at a reach scale, watershed considerations and location within the catchment provide additional important context. Reeves et al. (2016) suggested that with the tools currently available, widths can be more easily adjusted and justified for both wider and narrower buffers. Janisch et al. (2012) found that the amount of canopy cover retained in the riparian buffer was not a strong explanatory variable with regard to temperature in their study of forest harvest in small headwater catchments.

The fate of large wood in streams has been an important focus for aquatic scientists and managers in the western United States for decades (Richardson et al. 2012). Up until the 1980s, many managers were concerned about how wood in streams affected water quality and about how accumulations of wood in streams could sometimes block fish migration. These concerns led to instream wood removal programs (Mellina and Hinch 2009). By the 1980s, scientists more fully recognized wood's role in channel formation and maintenance (Forest Ecosystem Management Assessment Team 1993). As with stream temperature, the precautionary principle applied by the strategies to riparian reserves and riparian habitat conservation areas also ensured that the interim widths were set wide enough to encompass any trees that could be delivered to streams, especially the two-tree width for fish-bearing streams (Everest and Reeves 2007). Regarding the riparian width needed to ensure streamside wood delivery to streams, debate and scientific inquiry has continued since the strategies were adopted. Studies have been completed to help identify where wood in streams comes from (Reeves et al. 2003, Benda and Miller 2003) and the fate of wood once it is delivered above or to the stream (Beechie et al. 2000).

In addition to streamside delivery of large wood, disturbance combined with topography can deliver a significant percentage of wood from outside riparian management zones, especially steeper watersheds that are more dissected. Models have also been developed to help identify the likelihood of riparian trees being delivered to the stream channel (Benda and Miller 2003, Meleason et al. 2003, Pollock et al. 2012, Spies et al. 2013, Welty et al. 2002). Models focused on wood delivery from the riparian areas consider distance from the stream, median tree height, and the direction that trees fall. Benda et al. (2016) also discuss how to implement tree tipping, or manually felling trees into a stream, to balance the effects of thinning dense second growth stands to accelerate large wood development. Burton et al. (2016) found that instream wood loading is dominated by legacy wood during the late stages of decay and that silvicultural practices may be used to augment wood loading in headwater streams. Modeling completed by Meleason et al. (2003) found that greater than 90 percent of wood was contributed from within 100 feet of the stream edge for modeled conifer riparian stands in western Oregon and Washington.

Sediment and nutrient forest management practices such as road building and timber harvest have long been a concern regarding their potential to generate fine sediment and the subsequent effects on water quality (Beschta 1978). Altered sediment rates have also been linked to changes in stream condition and ultimately trout and salmon survival in cold-water streams (Jensen et al. 2009). Some activities that have led to degraded stream conditions and water quality, such as clearcutting next to streams and aggressive forest road building, are highly unlikely to occur today on National Forest System lands in the Forest Service Northern Region. Reductions in sediment and nutrient delivery have resulted from sequentially improving best management practices (Everest and Reeves 2007) and from regional strategies that have offered greater protection (U.S. Department of Agriculture and U.S. Department of the Interior 1995b). In recent decades, researchers interested in forest management and water quality have investigated the effectiveness of management policy and law (Brown et al. 1993, Cristan et al. 2016, Rashin et al. 2006). In general, more recent forest practice reviews have found very little unnatural introductions of total suspended sediments and nutrients when best management practices are properly installed before activities begin and are maintained throughout management efforts (Cristan et al. 2016, Sugden et al. 2012) NCASI 2012, Sudgen 2018. Depending on the geology of the planning area, sediment introduction from roads receiving little use can be quite low (Al-Chokhachy et al. 2016). Increased nitrogen levels may be an exception and may still contribute to levels outside of expected natural conditions (Gravelle et al. 2009). Standards and guidelines carried forward from existing strategies combined with conservation, restoration, and improvement strategies discussed elsewhere in this document should help to continue improving trends. Management practices that maintain suitable stream temperature, amounts of large wood, and levels of sediment and nutrients are also beneficial to aquatic and terrestrial wildlife species associated with riparian management zones.

Wildlife use riparian zones and wetlands disproportionately more than other areas and the density and diversity of wildlife are greater in riparian zones and wetlands than in other habitats (Oakley et al. 1985). Riparian zones strongly influence wildlife populations. Wildlife, including amphibians, reptiles, small mammals, and large mammals, use riparian habitats either year around or seasonally. Many amphibians and reptiles are restricted to aquatic and riparian habitats, while large mammals use riparian habitats seasonally. Some mammals, such as beaver and moose, rely on riparian and riverine habitats. The density, diversity, and structure of vegetation, combined with the landforms found in riparian zones and wetlands, provides wildlife with woody plant communities, surface water and soil moisture, structural diversity, and linear structure that creates migration corridors for many species.

Differences in Plan Direction and Land Allocation Between Alternatives

Land Allocation – Management Areas

Although some of the alternatives vary in pace or scale (for example yearly vegetation treatment targets), all of the work that will be done under any of the action alternatives will be subject to the same constraints. Although plan components are the same for action alternatives, land allocation and suitability, including recommended wilderness, Recreational Opportunity Spectrum (ROS), and Wild and Scenic Rivers do differ between some alternatives. Although actions likely to be taken and activities likely to occur under these alternatives may differ, the effects of are not expected to be different to aquatic habitat or organisms because of the universal application of ecosystem plan components under all action alternatives. The primary difference between each of the action alternatives is the pace at which forest restoration to natural range of variation is achieved. This pace varies somewhat between action alternatives, and the temporal aspect of this restoration was paramount in selecting a preferred alternative. The uncertainty associated with climate change necessitates reasonably rapid progress toward desired conditions if habitats and organisms on the national forest are to persist and acquire resilient adaptations.

Within the administrative boundary of the Nez Perce-Clearwater National Forest, approximately 30 percent of land is already in Management Area 1 (MA1), which includes designated wilderness areas, designated wild and scenic rivers, and national historic landmarks. Being in MA1 protects aquatic species and habitats by restricting management actions in these areas.

Approximately 36 percent of land is in Management Area 2 (MA2), which includes Idaho Roadless Areas, recommended wilderness, eligible and suitable wild and scenic rivers, designated research natural areas, proposed research natural areas, and the Gospel-Hump MA2 area. MA2 are unsuitable for timber production but can allow timber harvest for resource benefit. In practice, timber harvest generally does not occur in these areas. Between alternatives, the total number of acres in MA2 differs by 0.6 percent on the national forest, ranging from 36 percent to 36.6 percent. In addition, all areas recommended as wilderness or wild and scenic rivers under any of the action alternatives are already in the Idaho Roadless Rule areas and most of them have a wildland recreation or primitive theme, so being recommended as wilderness applies more restrictions on land use and provides more protection. Therefore, these areas are already largely protected from the management activities that would be likely to cause effects, and by becoming recommended wilderness areas, or wild and scenic rivers, a higher level of protection is applied.

Approximately 30 percent of land is in Management Area 3 (MA3). Between the alternatives, this amount varies 0.7 percent on the Nez Perce-Clearwater, ranging from 29.8 percent to 30.5 percent. The differences between the amount of land in MA3 between the alternatives is due to varying amounts of land allocated to MA2 (this is land in the one-quarter mile buffer for suitable Wild and Scenic Rivers) that was previously in MA3. Although riparian protection zones in these instances would increase in width to include one-quarter mile buffers, the existing stream buffers have been shown to be adequate to protect stream habitat. Although size of riparian management zones changes with these recommendations, the effective protection to stream function is expected to be similar between the existing buffers and future changes. MA3 lands are suitable for timber production and represent the area of the national forest that could potentially experience the vast majority of management effects to aquatic habitats and species. It is the MA3 that is most vulnerable to management effects. It is also the area that benefits least from land allocation decisions, which generally do not offer sweeping protections as in MA1 and MA2. Because so much land area (MA1 and MA2) in the national forest is already under protective measures through land allocation, MA3 receives the most benefits from the strong protections that the ecosystem plan components are designed to afford.

Because the ecosystem and species plan components in the revised forest plan do not differ between action alternatives, the guidance and protection that they afford will be the same under any of the action alternatives. In any cases where land allocation decisions may create threats or risks to aquatic species, the plan components of the revised forest plan are designed to provide ecological conditions to prevent habitat degradation, facilitate recovery of Endangered Species Act listed species, as well as allow for Species of Conservation Concern species to persist over the long term in the plan area. As a result, the suite of plan components in the revised plan are designed to provide the capacity to "maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area" (2012 Planning Rule § 219(a)(1)), as well as the capacity to "maintain or restore the diversity of ecosystems and habitat types throughout the plan area" (2012 Planning Rule § 219(a)(2)). As such, this section will primarily focus on how plan components are designed to carry forward or improve upon PACFISH and INFISH Biological Opinion (PIBO) direction that has been shown to have been effective in halting aquatic degradation at landscape scales. The effects section will be focused on seven categories of effects, including the current section, Differences in Plan Direction and Land Allocation Between Alternatives, Riparian Management Zones Environmental Consequences, Aquatic Habitat Environmental Consequences, Aquatic Species Environment Consequences, Cumulative Effects, Effects to Resource from Other Resources, and Comparison of No Action Alternative vs. Action Alternatives.

Recommended Wilderness

The different alternatives recommend varying numbers of rivers for Recommended Wilderness eligibility. The number of miles of stream that contain critical habitat for Endangered Species Act listed species range between 0 miles in Alternative X to 557 miles in the Alternative W (Table 126). The Preferred Alternative contains an intermediate amount of fish critical habitat, with 165 miles total in proposed Wild and Scenic River reaches. It is expected that stream habitat will benefit from being in Recommended Wilderness because of the restrictions on management associated with that land allocation.

Table 126. Miles of critical habitat for Endangered Species Act listed species that would be included in proposed wilderness areas by alternative in the revised forest plan for the Nez Perce-Clearwater National Forests.

Species	No Action	Alternate W	Alternate X	Alternate Y	Alternate Z	Preferred Alternate
Bull Trout	82	437	0	175	261	127
Steelhead	4	120	0	47	155	38

Species	No Action	Alternate W	Alternate X	Alternate Y	Alternate Z	Preferred Alternate
Sockeye	0	0	0	0	0	0
Fall Chinook	0	0	0	0	0	0
Total	**86**	**557**	**0**	**222**	**415**	**165**

Recreational Opportunity Spectrum (ROS) Suitability

The revised plan includes both summer and winter Recreational Opportunity Spectrum (ROS). Winter ROS is not expected to affect fish and aquatic species or their habitats because any activities that may occur would be done over a cover of snow and ice, with no potential for ground disturbance or sediment delivery to streams. As a result, the rest of this discussion will concern summer ROS. Suitability for summer recreational motorized trail travel is different between alternatives under ROS. Under the current 1987 Forest Plans, there were no ROS decisions. The Clearwater National Forest has a travel plan, and it essentially designates all of the national forest as closed to motorized travel unless there is a travel plan designated opening. The Nez Perce National Forest does not have a current travel plan and therefore is open to motorized travel except where specific closure orders are in place. Because there is no formal ROS for either national forest, suitability decisions under the action alternatives sometimes represent a change from the No Action Alternative. For the sake of discussion, this section will refer to suitability changes between the No Action Alternative and various alternatives; however, because there is currently no official suitability decision under the 1987 plans, these discussions must be understood in that context. Although these changes do not have direct or indirect effects (as no federal action occurs), the differences in suitability decisions between alternatives construct different frameworks designed to guide future land management decisions. For example, areas where suitability will change allowable use from motorized to non-motorized (Table 127) would be expected to see either beneficial or no effects due to an incremental increase in protection offered by that suitability determination. Areas where a suitability decision will change allowable use from non-motorized to motorized (Table 128) could potentially, in the future, experience potential adverse effects if subsequent management decisions establish motorized trails in those areas, and if those trails cross streams or are otherwise located where they present risk to aquatic organisms.

The number of stream miles containing critical habitat in areas where suitability would lead to a change from open for motorized to not suitable for motorized varies between alternative and ranges from 0 miles of sockeye and fall Chinook salmon critical habitat in Alternative X to 231 miles of bull trout habitat in Alternative Z. The Preferred Alternative contains various amounts of miles of critical habitat that would be affected (Table 127). Because these areas are already in Idaho Roadless Rule Area, they are already subject to some level of protection based on their designated theme, and the change to non-motorized is expected to strengthen protections.

The number of miles of critical habitat in areas where suitability would change use from closed to motorized to suitable for motorized varies between alternatives and ranges from 0 in several alternatives to 165 miles of bull trout habitat in the preferred alternative, which also contains 107 miles of steelhead habitat that would be affected (Table 128). For bull trout, when changes both directions are combined, it represents a net change that ranges from 7 percent less non-motorized in Alternative X to 9 percent more non-motorized bull trout critical habitat in Alternative W. The Preferred Alternative results in 3 percent less bull trout habitat being in areas not suitable for motorized recreation. For steelhead, when changes both directions are combined, it represents a net change that ranges from 1 percent less steelhead critical habitat being in areas not suitable for motorized in Alternative X to 10 percent more in Alternative Z. The Preferred Alternative results in 1 percent more steelhead habitat being in areas not suitable for motorized recreation. This analysis was only relevant for these two species because there is no official critical habitat layer available for Snake River spring and summer Chinook, and Recreational Opportunity Spectrum (ROS) did not affect any Snake River Sockeye or Snake River Fall Chinook critical habitat.

Table 127. Miles of critical habitat for Endangered Species Act listed fishes that would change from motorized to non-motorized under Recreational Opportunity Spectrum by alternative. NA = not applicable.

Species	No Action Alternative	Alternative W	Alternative X	Alternative Y	Alternative Z	Preferred Alternative
Columbia River Bull Trout	NA	231	94	147	148	128
Snake River Spring/Summer Chinook	NA	NA	NA	NA	NA	NA
Snake River Fall Chinook	NA	0	0	0	0	0
Snake River Summer Steelhead	NA	147	106	144	149	114
Snake River Sockeye	NA	24.5	24.5	24.5	24.5	24.5

Table 128. Miles of critical habitat for Endangered Species Act listed fishes that would change from non-motorized to motorized under Recreational Opportunity Spectrum by alternative. NA = not applicable.

Species	No Action Alternative	Alternative W	Alternative X	Alternative Y	Alternative Z	Preferred Alternative
Columbia River Bull Trout	NA	97	188	47	41	165
Snake River Spring/Summer Chinook	NA	NA	NA	NA	NA	NA
Snake River Fall Chinook	NA	0	0	0	0	0
Snake River Summer Steelhead	NA	101	114	30	30	107
Snake River Sockeye	NA	0	0	0	0	0

Table 129. Percent change in critical habitat miles affected by Revised Plan Recreational Opportunity Spectrum suitability on the Nez Perce-Clearwater National Forest.

Bull Trout	Species	Percent Change to Motorized Suitability	Percent Changing to Non-Motorized Suitability	Net Change (Percent Non-Motorized)
Preferred Alternative	Bull Trout	12	9	-3
Alternative W	Bull Trout	7	16	9
Alternative X	Bull Trout	13	7	-7
Alternative Y	Bull Trout	3	10	7
Alternative Z	Bull Trout	3	10	8
Alternative P	Steelhead	9	9	1
Alternative W	Steelhead	8	12	4

Bull Trout	Species	Percent Change to Motorized Suitability	Percent Changing to Non-Motorized Suitability	Net Change (Percent Non-Motorized)
Alternative X	Steelhead	9	9	-1
Alternative Y	Steelhead	2	12	9
Alternative Z	Steelhead	2	12	10

Because Recreational Opportunity Spectrum (ROS) suitability does not have any effects on aquatic habitat until subsequent project level decisions are made, any potential effects and effects analysis would happen at the project level. However, there are several considerations that can provide context and direction for future project decisions. One is that under the preferred alternative, the miles of critical habitat that could be adversely affected by ROS suitability decisions (represented by a negative value in Table 129) are very small (3 percent) and are limited to bull trout. It is important to note that this analysis does not give exact, finite numbers or percentages that would change, because of some overlap between critical habitat layers for bull trout and steelhead, but it is useful for comparison purposes between alternatives, and must be interpreted in that context. In addition, there are not only protective aquatic plan components, but recreation (aquatic and riparian) plan components that are specifically designed to address management of any potential environmental consequences, including FW-GDL-ARREC-03, FW-GDL-ARREC-04, FW-GDL-ARREC-05, FW-GDL-ARREC-06, as well as a suitability plan component (FW-SUIT-ROS-01) which are all designed to provide protection by constraining or guiding motorized trail construction.

Idaho Roadless Rule Areas

Although the forest plan does not make Idaho Roadless Rule (IRR) decisions, many of the plan decisions tier to or build upon previous decisions made under the IRR. These decisions include recommendations for wilderness, as well as Recreational Opportunity Spectrum (ROS) suitability decisions.

Areas recommended for wilderness under all action alternatives are all in IRR areas. It is important to understand the relationship between IRR, recommended wilderness, and forest plans. Idaho Roadless Rule is federal law and supersedes forest plans. However, forest plan decisions that recommend wilderness tier to the Wilderness Act of 1964, which supersedes by virtue of restrictions on anything that affects wilderness character. Therefore, although technically the national forest could build roads and harvest timber in IRR, and IRR still applies to recommended wilderness, it would have to be approved by the regional forester, and exceptions and permissions depend somewhat on the IRR theme. The Final Rule and record of decision pertaining to the IRR is clear that the intent of exceptions to timber harvest restrictions were expected to be limited to less than 4 percent of harvest volume from National Forest System lands in Idaho, with most of that expected to occur in the adjacent Panhandle National Forest (FR: 61456, 36 CFR 294). In practice, that projection has been close to accurate on the Nez Perce-Clearwater National Forest, where timber harvested on IRR lands has represented approximately 180 acres per year, or 0.016 percent of National Forest System lands annually. For more information about this, refer to the Special Areas section of this document. However, when recommended for wilderness, the intent is that the land will be designated by Congress, added to the list of designated wilderness, and subsequently, the Wilderness Act of 1964, prevents any activities that affect wilderness character. So, although IRR lands were already included in MA2, upon wilderness recommendation, the land remains in MA2, and there is theoretically increased protection in the recommended wilderness plan decision. All of the recommended wilderness areas in the preferred alternative are already IRR primitive or backcountry restoration themes (the most restrictive themes, which require regional forester approval for treatments or ground disturbing activities) except West Fork Meadow Creek, which is currently wildland recreation (the most permissible), so once recommended, it is expected that a request would be submitted to the IRR council for a change of theme to make it consistent with the forest plan decision.

In practice then, the difference between the more restricted IRR themes and recommended wilderness regarding motorized use is that IRR themes do not restrict motorized use, while it is restricted under recommended wilderness except for administrative use and is prohibited once designated by Congressional action. On the Nez Perce-Clearwater National Forest, there have been limited instances of old skid roads being converted into motorized trail loops in IRR themes, but this activity has not been widespread. Future locations of new roads and trails on the national forest would be determined by programmatic decisions such as a travel plan or individual project level decisions. These would undergo the appropriate consultation with U.S. Fish and Wildlife Service and National Marine Fisheries Service if required, as well as National Environmental Policy Act (NEPA). As a result of plan component requirements that preclude retarding progress toward attainment of desired conditions, as well as the need for individual project level consultation and NEPA analysis, it is expected that any potential negative effects will be explored, disclosed, and mitigated for at the project level if future projects expand motorized trail use in these areas. In addition, there are specific suitability plan components including MA2-GL-IRA-01, MA2-DC-IRA-01-05, MA2-STD-IRA-01 that are designed to direct management of IRR areas on the national forest in order to minimize environmental consequences that could occur through management of IRR areas. For more discussion of the Idaho Roadless Rule, see the Sustainable Recreation section of this document.

Wild and Scenic Rivers

The different alternatives recommend varying numbers of rivers for Wild and Scenic suitability and eligibility ranging from 0 to 37 suitable and 0 to 29 eligible. Miles of stream that contain critical habitat for Endangered Species Act listed species range between 391 total in Alternative X to 980 in the No Action Alternative (Table 130). The Preferred Alternative contains an intermediate amount of fish critical habitat, with 502 miles total in proposed Wild and Scenic River reaches. This is primarily because the Preferred Alternative proposes fewer rivers for wild and scenic status; the number of rivers eligible for wild and scenic river designation would decrease from 29 under the 1987 plan to 12 under the proposed plan (11 suitable and 1 eligible). However, stream and riparian protections would not be compromised because the quarter-mile protection corridor (cumulatively equates to the 22,658 acres that would change from Management Area 2 to Management Area 3) afforded by the National Wild and Scenic Rivers System Act is larger than necessary to protect stream functions, and the proposed riparian management zone (RMZ) distances would offer sufficient protection as determined by PACFISH/INFISH. Furthermore, RMZ plan components provide guidance for management activities to reestablish disturbance patterns in areas where it is lacking to restore riparian processes according to proposed RMZ desired conditions (FW-DC-RMZ-01, 02). Physical or biological feature (PBF) 4 in particular would indirectly benefit from management area allocations as larger areas of recommended wilderness and RMZ guidelines that are equally as protective as PACFISH/INFISH protections would contribute to the types of natural processes that provide complex habitat, natural cover, and refugia.

Table 130. Miles of critical habitat for Endangered Species Act listed fish that on the Nez Perce-Clearwater National Forest that would be located in proposed Wild and Scenic Rivers under each forest

plan revision alternative. Snake River spring and summer Chinook were not included because there is no critical habitat shapefile available from National Marine Fisheries Service.

Species	No Action Alternative	Alternative W	Alternative X	Alternative Y	Alternative Z	Alternative P
Columbia River Bull Trout	547	272	285	362	488	264
Snake River Steelhead	348	152	106	187	290	154
Snake River Fall Chinook	11	11	0	11	11	11
Snake River Sockeye	73	73	0	73	73	73
Total	980	508	391	633	863	502

By Alternative

No Action Alternative

Several species of fish would continue to experience an increase in risk of habitat destruction from high severity fires due to forest succession, fire suppression, and climate change. Timber harvest targets are currently set at 50 to 60 million board feet (MMBF) annually, and the maximum opening size is 40 acres without approval from the regional forester. Emphasis for Endangered Species Act listed fishes would continue to be on minimizing sediment input to streams and continuing to provide shade through riparian buffers. Fish habitat security would remain high throughout Idaho Roadless Rule areas, wilderness areas, and recommended wilderness. Management would continue with PACFISH/INFISH as the guidance that ensures maintenance of aquatic ecosystem integrity. These measures would continue to maintain the current amount secure fish habitat and are expected to continue to provide for passive restoration in degraded streams.

Aquatic habitats would be provided for in a similar manner as in the proposed plan components and alternatives because PACFISH and INFISH provide similar levels of protection for aquatic habitats as those in the Aquatic Ecosystems section of the Land Management Plan. Several rivers would remain eligible for wild and scenic status and management of these eligible rivers would continue to provide habitats for aquatic species. Eligible acres of wild and scenic river corridors would be 172,710 acres. These rivers would continue to be managed to protect the outstandingly remarkable values that make them eligible. This direction may help some aquatic species and may hinder active restoration for them in other areas. There would be no change in the amount of designated wild and scenic rivers.

The amount of recommended wilderness would remain the same with the Hoodoo, Mallard-Larkin, and Selway additions remaining recommended wilderness. The Hoodoo area would stay intact in its current form and not be reduced, as in other alternatives. The amount of recommended wilderness proposed under the No Action Alternative is intermediate to other alternatives for recommended wilderness.

Within recommended wilderness, activities to restore vegetation would continue to be restricted. This would continue to inhibit most restoration activities in the current recommended wilderness. This would impact the national forest’s ability to proactively restore these habitats. However, restoration activities in many other Idaho Roadless Rule (IRR) areas that are currently in the backcountry restoration theme would remain in this theme, which allows restoration and improvements. Restoration would only be achieved in recommended wilderness through wildfire, which can vary in severity and effects to Endangered Species Act (ESA) listed fish. Under the 1987 plans, the management direction for wildfire is to confine, contain, and control wildfire. Under the new plan direction, wildland fire would be more permissive in many areas of the Nez Perce-Clearwater.

Both current recommended wilderness and IRR areas would continue to provide for ESA listed fishes and aquatic sensitive species. Use of game carts, chainsaws, mechanized travel such as bicycles, and aircraft would continue to be prohibited in recommended wilderness.

Alternative W

Alternative W proposes the most wilderness areas (totaling 856, 932 acres), designates 12 rivers as suitable for wild and scenic rivers, provides for motorized access in all IRR with a backcountry restoration theme. It also provides for the most non-motorized access because of the high amount of recommended wilderness. It establishes a potential timber harvest of 221 to 241 million board feet (MMBF) annually, has a maximum opening size of 207 acres, and is designed to meet forest vegetation desired conditions within 30 years when timber harvest, prescribed fire, and natural disturbance are accounted for.

Alternative W reaches desired vegetation conditions faster than the No Action Alternative and slightly slower than Alternative X. Thus, it has a relatively more aggressive schedule for restoring the system back to the desired conditions, which are based upon the natural range of variation (NRV). For fish, this quicker paced schedule would reduce the risk of high severity wildfire quicker than the No Action Alternative. While the pace may be quicker, the total amount of restored forest does not differ much overall among the alternatives.

This makes sense because the desired conditions for vegetation do not vary by action alternatives, rather the pace or the methods of achieving those desired conditions vary. However, vegetation management would contribute substantially to forage as well, especially within Management Areas 2 and 3. Under Alternative W, forest conditions would trend towards NRV and are expected to meet the needs of many aquatic species. The more proactive schedule in Alternative W would allow more areas to be targeted to increase the amount of the national forest restoration which moves the landscape toward the natural range of variation (NRV). Proactive management through wildland fire would occur more proactively under Alternative W in Idaho Roadless Rule (IRR) areas, especially within backcountry restoration themed areas. Management of natural fires in designated wilderness would still be possible at similar rates as they have been under the No Action Alternative. The ability of the Nez Perce-Clearwater to achieve desired amounts of stream restoration would be hindered within recommended wilderness as explained below.

In Alternative W, slightly more areas were identified as suitable for motorized uses compared to the No Action Alternative. This could affect fish security in some areas, especially those that would be suitable for motorized uses, because public access for fishing could be increased. The percentage of the planning area that is suitable for summer motorized uses would be 47 percent, an increase of about 2 percent suitable for motorized use from the No Action Alternative. Forty-eight percent of the plan area would be suitable for winter motorized travel, while 52 percent would be unsuitable. Maps of the alternatives for the summer and winter recreation opportunity spectrum (ROS) can be found in Appendix A. Areas suitable for various durations and seasons of motorized uses could allow more access by anglers and recreationists.

Endangered Species Act (ESA) listed and Species of Conservation Concern (SCC) aquatic species would be provided for in a similar manner in all alternatives as measures in aquatic ecosystem plan components are similar to those in PACFISH/INFISH. However, under a more aggressive schedule of treatments, more potential impacts could occur under this alternative. Alternative W proposes the greatest number of rivers as suitable wild and scenic rivers. The proposed area of suitable wild and scenic river corridor is more than those eligible under the No Action Alternative. Eligible acres of wild and scenic river corridors would be 172,710 acres under the No Action Alternative versus 65,650 acres under Alternative W. This direction may help some fish species but may hinder active restoration for them in other areas under this alternative compared to in the No Action Alternative. There would be no change in the amount of designated wild and scenic rivers.

The amount of recommended wilderness would increase the most under Alternative W. In addition to the Hoodoo, the Mallard-Larkin, and the Selway additions, this alternative would add Bighorn-Weitas, North Lochsa Slope, East Meadow Creek, Moose Mountain, Rapid River, North Fork Spruce-White Sands, Sneakfoot Meadows, Meadow Creek-Upper North Fork, and West Meadow Creek. This amount of recommended wilderness would be the most compared to the other alternatives. The amount of recommended wilderness would have environmental consequences on ESA listed fishes and aquatic sensitive species, as described below.

Under Alternative W, more fish populations would be included in recommended wilderness than other alternatives with the addition of 10 recommended wilderness areas, totaling approximately 857 acres. More spawning and rearing habitat will thus be included in recommended wilderness under this alternative. Fish populations in these populations would benefit from the additional recommended wilderness area because they would not be subject to managements decisions that could allow motorized use under Alternative W. Although all recommended wilderness is already in IRR themes, some IRR themes allow motorized trails, whereas recommended wilderness does not. This would decrease the potential for sediment input from motorized trails, and access to fish by anglers would be more difficult. On the other hand, the ability to connect fisheries habitats within the plan area or the ability to improve fisheries habitat conditions through active management would be constrained within recommended wilderness under this alternative.

Alternative X

Alternative X recommends zero areas for wilderness, and zero suitable wild and scenic rivers. It allocates the most land as suitable for motorized access in summer and winter. It establishes a potential timber harvest of 241 to 261 million board feet (MMBF), has a maximum opening size of 207 acres, and is designed to meet forest vegetation desired conditions within 20 years when timber harvest, prescribed fire, and natural disturbance are accounted for.

Alternative X reaches desired vegetation conditions the fastest out of all the alternatives and slightly faster than Alternative W. Thus, it has the most aggressive schedule for restoring the system back to the desired conditions, which are based upon the natural range of variation (NRV). For fish, this quicker-paced schedule would improve aquatic resources quicker than any other alternative. While the pace may be quicker, all alternatives seek to achieve the same desired forest conditions.

Under Alternative X, forest conditions would trend towards desired conditions at a rapid pace. Proactive management through wildland fire would occur more under Alternative X in Idaho Roadless Rule (IRR) areas, especially within backcountry restoration themed areas. As no areas would be identified as recommended wilderness, this alternative has the least constraints on improving stream habitat. Management of natural fires in designated wilderness would still be possible at similar rates as they have been under the No Action Alternative.

In Alternative X, more areas were identified as suitable for motorized uses compared to the No Action Alternative. This could contribute to public access and more risk of sediment delivery to streams use in some areas, especially those that would be suitable for motorized uses. The percentage of the planning area that is suitable for summer motorized uses would be 58 percent, an increase of about 13 percent suitable for motorized use compared to the No Action Alternative. Seventy percent of the plan area would be suitable for winter motorized travel, while 30 percent would be unsuitable. Maps of the alternatives for summer and winter recreation opportunity spectrum (ROS) can be found in Appendix A. Areas suitable for motorized uses could see an increased risk of construction of unauthorized routes, which could potentially degrade stream conditions if such routes are near to or cross streams.

Aquatic habitats would be provided for in a similar manner in all alternatives as measures in aquatics plan components are similar to PACFISH/INFISH. However, under a more aggressive schedule of treatments, there is an increased risk of potential impacts that could occur under this alternative. Alternative X proposes no rivers as suitable for wild and scenic rivers. The proposed area of suitable wild and scenic river corridor is more than those eligible under the No Action Alternative. Eligible acres of wild and scenic river corridors would be 172,710 acres under the No Action Alternative versus zero acres under Alternative X. There would be no change in the amount of designated wild and scenic rivers.

The amount of recommended wilderness would be none under Alternative X, which would reduce the amount of recommended wilderness compared to the No Action Alternative. The Hoodoo, the Mallard-Larkin, and the Selway additions would no longer be recommended wilderness. The amount of recommended wilderness would be the least compared to the other alternatives. The amount of recommended wilderness would have environmental consequences to fish, as described below. The amount of designated wilderness would not change under this alternative.

Under Alternative X, no new fish major population groups or critical habitat would be included in recommended wilderness. On the other hand, the ability to do stream restoration projects through active management would be the most permissible in this alternative.

The ability of the Nez Perce-Clearwater to pursue active management to achieve desired conditions would be most proactive under this alternative. Therefore, the ability of the national forest to conduct stream restoration activities intended to move toward desired conditions would be maximized. Under this alternative all areas are open to mechanized travel. Allowing mechanized travel, such as bicycles, could have slight detrimental consequences to fish if mountain bikes increase access to stream reaches farther from roads. Under this alternative, this activity would be allowed in the largest area. However, mechanized travel is not intensive in the plan area at the present time.

Alternative Y

Alternative Y recommends four Idaho Roadless Areas (IRR) for wilderness (309,332 acres) and finds suitable 14 wild and scenic rivers. Motorized access would be expanded by opening backcountry themed roadless areas including Bighorn Weitas and Pot Mountain. It establishes a potential timber harvest of 130 to 150 million board feet (MMBF) annually with a maximum opening size of 207 acres and is designed to meet forest vegetation desired conditions within 50 years when timber harvest, prescribed fire, and natural disturbance are accounted for.

The less proactive schedule in Alternative Y would allow fewer areas to be targeted to increase the quality of the stream habitat by restoring forests to towards their natural range of variation (NRV). Proactive management through wildland fire would be moderate under Alternative Y in IRR areas compared to Alternatives W and X. Management of natural fires in designated wilderness would still be possible at similar rates as they have been under the No Action Alternative.

In Alternative Y, slightly fewer areas were identified as suitable for motorized uses compared to the No Action Alternative. This could benefit fish habitat in some areas, especially those that would not be suitable for motorized uses. The percentage of the planning area that is suitable for summer motorized uses would be 44 percent, a decrease of about 1 percent suitable for motorized use from the No Action Alternative. Sixty-two percent of the plan area would be suitable for winter motorized travel, while 39 percent would be unsuitable. Maps of the alternatives for summer and winter recreation opportunity spectrum (ROS) can be found in Appendix A. Areas suitable for motorized uses could affect fish and stream quality.

Aquatic habitats would be provided for in a similar manner in all alternatives as aquatics plan components and contain similar protections as measures in PACFISH/INFISH. Under a less proactive schedule of treatments, fewer potential impacts could occur under this alternative. Alternative Y proposes intermediate amounts of rivers as suitable as wild and scenic. The proposed area of suitable wild and scenic river corridor is more than those eligible under the No Action Alternative. Suitable acres of wild and scenic river corridors would be 100,623 acres under Alternative Y. These acres would benefit fish species, but may be neutral to others, as the quarter-mile riparian buffer is much larger than what has been shown to be effective to protect stream resources. Wild and Scenic suitability is not expected to hinder habitat enhancement for aquatic species because riparian treatments can still occur for resource benefit to move toward desired conditions in the larger stream buffer widths. There would be no change in the amount of designated wild and scenic rivers.

The amount of recommended wilderness would decrease under Alternative Y versus the No Action Alternative because the Hoodoo area would decrease from a boundary change. The change in the amount of recommended wilderness would have environmental consequences on fish and aquatic species, as described below.

The ability of the Nez Perce-Clearwater to pursue active management to achieve desired conditions would be similar to the No Action Alternative, more than Alternative W, and less than in Alternative X. The ability of the national forest to do active stream restoration in Management Area 2, as a result of achieving desired vegetation conditions, would be allowed under this alternative. Restoration would be achieved in recommended wilderness through wildland fire, which may not occur in areas expected to produce the best aquatic response.

Current recommended wilderness, designated wilderness, and Idaho Roadless Rule (IRR) areas would continue to provide high levels of protection for Endangered Species Act listed and Species of Conservation Concern species in Management Areas 1 and 2. Under Alternative Y, these species would be slightly more accessible to the public than in the No Action Alternative. Under this alternative, mechanized travel is prohibited in recommended wilderness, as well as game carts. The prohibition of mechanized travel, such as bicycles, would have slight benefits to fish because mountain bikes can increase public access to streams farther from roads. Under this alternative, this activity would be prohibited. However, mechanized travel is not intensive in the plan area at the present time.

Alternative Z

Alternative Z recommends 10 IRR areas (totaling 569,755 acres); however, they would be managed to allow winter motorized and mechanized travel, which would change if Congress designated them as wilderness. It designates 37 rivers as suitable for wild and scenic rivers. It contracts motorized access by finding that West Meadow Creek is not suitable for motorized travel. It establishes timber harvest levels of between 8 and 100 million board feet (MMBF) annually with a maximum opening size of 207 acres and is designed to meet forest vegetation desired conditions within 100 or more years when timber harvest, prescribed fire, and natural disturbance are accounted for. It also has additional snag requirements for timber sales.

Alternative Z would reach desired vegetation conditions at a similar rate to the No Action Alternative but slower than Alternatives W and X. Thus, it has a relatively more relaxed schedule for restoring the system back to the desired conditions, which are based upon the natural range of variation (NRV). For fish, this more moderately paced schedule would continue to expose aquatic habitats to an increased risk of high severity fire.

Proactive management through prescribed fire and managed wildland fire would be similar to the No Action Alternative under Alternative Z but slower in Idaho Roadless Rule areas compared to Alternatives W and X. Management of natural fires in designated wilderness would still be possible at similar rates as they have been under the No Action Alternative.

In Alternative Z, slightly less areas were identified as suitable for motorized uses compared to the No Action Alternative. This could aquatic habitat in some areas, especially those that would not be suitable for motorized uses. The percentage of the planning area that is suitable for summer motorized uses would be 43 percent, a decrease of about 2 percent suitable for motorized use from the No Action Alternative. Seventy percent of the plan area would be suitable for winter motorized travel, while 30 percent would be unsuitable. Maps of the alternatives for summer and winter recreation opportunity spectrum (ROS) can be found in Appendix A.

Aquatic habitats would be provided for in a similar manner in all alternatives as aquatics plan components provide similar protection to measures in PACFISH and INFISH. Under a less proactive schedule of treatments, fewer potential impacts could occur under this alternative. Alternative Z proposes the most amounts of rivers as suitable as wild and scenic. The proposed area of suitable wild and scenic river corridor is more than those eligible under the No Action Alternative. Suitable acres of wild and scenic river corridors would be 149,691 acres under Alternative Z. These acres would help some aquatic species, be neutral to others, and active habitat enhancement efforts in streams would be more difficult. There would be no change in the amount of designated wild and scenic rivers.

Alternative Z is the second highest alternative for the amount of recommended wilderness compared to the other alternatives. The alternative would include the Hoodoo, Mallard-Larkins, East Meadow Creek, Rapid River, Meadow Creek-Upper North Fork, North Fork Spruce-White Sands, Sneakfoot Meadows, Rawhide, and Pot Mountain Idaho Roadless Rule (IRR) areas. This is the only alternative that would include Pot Mountain. The change in the amount of recommended wilderness would have environmental consequences on fish and aquatic species as described below.

Under Alternative Z, more fish populations would be included in recommended wilderness than in all but Alternative W. Access to fish by anglers would be more difficult in these recommended wilderness areas. The ability to connect fish habitats within the plan area or the ability to improve fish habitat conditions through active management would be constrained within recommended wilderness under Alternative Z. Thus, this alternative restricts anglers' access and contains the opportunity for the national forest to conduct active stream restoration.

The ability of the Nez Perce-Clearwater to pursue active management to achieve desired conditions would be constrained in this alternative more than all but Alternative W because of the high amount of recommended wilderness, which would change many areas that are currently in the backcountry restoration theme to the backcountry recreation theme. Active management for restoration purposes is strongly restricted in this theme. Therefore, the ability of the national forest to do active stream restoration in 474,288 acres of recommended wilderness would be highly restricted under this alternative. This would not be an insignificant amount. This would impact the Nez Perce-Clearwater's ability to proactively restore these habitats for fishes. Restoration would only be achieved in recommended wilderness through wildfire, which may not occur in areas expected to produce the best habitat response. In addition, wildland fire would be largely unsuppressed, which increases the risk of fires burning riparian areas.

Current recommended wilderness, designated wilderness, and IRR areas would continue to provide for Endangered Species Act listed and Species of Conservation Concern species. Under Alternative Z, the higher amounts of recommended wilderness would be better for these species because of the limited access it would provide.

Under this alternative, mechanized travel is allowed in recommended wilderness, as well as game carts. Allowing mechanized travel, such as bicycles, would have slight detrimental effects to fish because mountain bikes have been documented to increase public access to streams farther from roads. Under this alternative, this activity would be allowed. However, mechanized travel is not intensive in the plan area at the present time.

Preferred Alternative

The preferred alternative recommends three wilderness areas, including parts of four IRR areas (totaling 258,210 acres). It finds 11 rivers suitable for wild and scenic rivers, and one river, the Little North Fork Clearwater, would remain eligible. It expands motorized access in both summer and winter, establishes timber harvest of between 190 and 210 million board feet (MMBF) annually with a maximum opening size of 207 acres, and is designed to meet forest vegetation desired conditions in 30 to 35 years when timber harvest, prescribed fire, and natural disturbance are accounted for.

The preferred alternative adopts a quicker pace to achieve desired vegetation conditions and would reach desired conditions faster than all alternatives except Alternative X. As a result, it is expected to restore the landscape back to conditions based on natural range of variation (NRV) in a shorter time frame. For fish, this more aggressively paced schedule is expected to improve habitat by changing the hydrologic cycle to one that more closely resembles historical conditions on the national forest. As objectives for fisheries habitat improvement are nested within efforts to restore vegetation back to a natural range of variability, the alternatives that accelerate the pace of aquatic restoration are expected to be more beneficial to fish than alternatives with a slower restoration pace.

In the preferred alternative, more areas were identified as suitable for motorized uses which could affect fish habitat use in some areas. For example, there is anecdotal evidence that in recent years there has been an increase of anglers targeting bull trout in the North Fork Clearwater River. Joubert et al. (2019) found that a greatly increased duration of air exposure (that they felt replicated anglers photographing memorable fish) can greatly increase bull trout mortality. However, their air exposure (112 seconds) was likely much longer than what fish typically undergo in a catch and release fishery (McCarrick et al 2019). However, if increased motorized access could lead to higher angling effort, more anglers could hypothetically lead to some measure of higher mortality of bull trout. Although apparent declines in bull trout redds were observed for several years in the North Fork for unknown reasons, the most recent data from Idaho Department of Fish and Game (IDFG) suggests that a static trend in that drainage. However, under the Preferred Alternative, motorized trail suitability increases in the North Fork, and therefore, if trails are planned that cross or otherwise provide access to streams, fishing access may increase, which could increase bull trout mortality if anglers remove memorable or trophy fish from water for prolonged periods, or if trails contribute sediment to rivers. However, even if trails were planned and constructed, the plan component (MA2-GDL-WL-05) would protect against spur trails and would likely limit most tributary access. In addition, float anglers generally rely on the main North Fork Road for river access, because it is impractical to transport boating equipment for a float trip via all-terrain vehicle, so an increase in motorized trails may not facilitate a meaningful increase in access because of the logistics associated with transporting boats.

The Preferred Alternative recommends an intermediate amount of land for recommended wilderness (3 additional) for a total of 258,210 acres. The ability of the Nez Perce-Clearwater to pursue active management to achieve desired conditions would be constrained in this alternative more than all but Alternative W because of the high amount of recommended wilderness, which would change many areas that are currently in the backcountry restoration theme to the backcountry recreation theme. Active management for restoration purposes is strongly restricted in this theme. Therefore, the ability of the national forest to do active stream restoration in 258,210 acres of recommended wilderness would be somewhat restricted under this alternative. This would not be an insignificant amount. This would impact the Nez Perce-Clearwater's ability to proactively restore these habitats for fishes. Restoration would only be achieved in recommended wilderness through wildfire, which may not occur in areas expected to produce the best habitat response. In addition, wildland fire would be largely unsuppressed, which increases the risk of fires burning riparian areas.

Riparian Management Zones Environmental Consequences

Background

Riparian Habitat Conservation Areas in the No Action Alternative and Riparian Management Zones in the action alternatives are portions of watersheds where riparian-associated resources receive primary emphasis, and management activities are subject to specific standards and guidelines. These areas consist of riparian and terrestrial vegetation adjacent to streams, wetlands, and other bodies of water, helping to maintain the integrity of aquatic ecosystems and provide for wildlife habitat use and connectivity. Ponds, lakes, wetlands, streams, and other water features have been identified and mapped across the Nez Perce-Clearwater.

Effects of Forestwide Direction on Riparian Areas

No Action Alternative

PACFISH amended the Nez Perce and Clearwater Forest Plans and is unchanged from its original wording in the No Action Alternative. INFISH amended the Clearwater Forest Plan in areas not supporting anadromous fish, which included the Upper and Lower North Fork Clearwater subbasins above Dworshak Dam and the Palouse River. Both strategies underwent programmatic consultations in 1995 for listed salmon and again in 1998 for listed steelhead and bull trout and additional requirements in the resulting Biological Opinions legally became part of the strategies and were implemented on the Nez Perce and Clearwater National Forests. Both the strategies and their Biological Opinions reduce the risk to watersheds and riparian and aquatic resources by improving riparian zone protections. Riparian habitat conservation areas are established as management zones bordering streams, wetlands, and other water features. They are not mapped as designated management areas, but their delineation at the site-specific level is described in plan direction, including their minimum width. Table 131 displays the riparian habitat conservation area widths. These widths could be adjusted in some cases, based on site-specific conditions, but these are the widths that would be used for the purpose of analysis at the programmatic level.

Table 131. Minimum width of riparian habitat conservation areas under the No Action Alternative.

Water Feature Type	Minimum Width (ft) on each side of the stream, pond, wetland, or landslide-prone area
Category 1 – Fish bearing stream	300
Category 2 – Perennial non-fish bearing stream	150
Category 3 – Constructed reservoirs, ponds, lakes, and wetlands >1 acre	150
Category 4 – seasonally flowing or intermittent streams, pond, lakes, wetlands < 1 acre, landslides and landslide prone areas in KEY/PRIORITY watersheds	100
Category 4 – seasonally flowing or intermittent streams, pond, lakes, wetlands < 1 acre, landslides and landslide prone areas NOT in KEY/PRIORITY watersheds	50

Data Source: 1987 Forest Plans (U.S. Department of Agriculture 1987b, a), as amended by PACFISH and INFISH.

It is important to note that the 1998 PACFISH and INFISH Biological Opinions required all streams within the range of Endangered Species Act listed steelhead to be considered a Key or Priority watershed, so, following 1998, nearly all Category 4 riparian habitat conservation areas were 100 feet. Exceptions were in the North Fork Clearwater subbasins in subwatersheds not considered priority for bull trout and the Palouse River.

Riparian habitat conservation areas are classified as not suitable for timber production based on the determination that a scheduled flow of commercial timber products using a rotation age could not be expected to occur on these lands because of management requirements and desired conditions for other resources associated with riparian habitat conservation areas. Timber harvest is allowable within riparian habitat conservation areas if conducted to achieve objectives for the stream and riparian habitat conservation areas.

Riparian areas are considered their own management area in both the Nez Perce and Clearwater Forest Plans. Forestwide goals and direction in the 1987 plans address water quality, stream channel integrity, diversity of plant communities, riparian-dependent wildlife, and other features associated with aquatic and riparian areas that provide protection for the riparian-associated resources and values. They include direction allowing no management in riparian areas that would cause detrimental changes in water temperature or chemical composition, blockages of water courses, or deposits of sediment that seriously and adversely affect streams or fish. Also included is direction to manage riparian areas to maintain cover and security for riparian-dependent species with emphasis on maintaining and enhancing habitats for threatened and endangered species.

Nothing in the PACFISH and INFISH amendments and their Biological Opinions contradicts this 1987 plan direction. Rather, PACFISH and INFISH provided more refined and detailed standards and guidelines, established interim widths for riparian habitat conservation areas that required Watershed Assessment to adjust. These interim widths were generally much wider than those used during project planning and implementation prior to the amendments, described the concept of Watershed Analysis and appropriate use, and included detailed riparian goals and riparian management objectives. Implicit in these amendments was the concept of "do not retard;" in other words, they were used to maintain aquatic conditions until such time as site-specific direction were developed through forest planning. Originally, they were intended to provide temporary guidance for 18 to 36 months until a restoration decision similar to Northwest Forest Plan could be completed (Interior Columbia Basin Ecosystem Management Project [ICEBMP]). A decision was never made, and instead, ICEBMP guidance was developed in 2003 (amended in 2014) to guide management actions until further direction was provided through future forest plan revisions.

Under the No Action Alternative, these protections would stay in place, and the terrestrial and aquatic habitats within the riparian habitat conservation areas would continue to be protected. In addition, riparian habitat conservation areas established for wetlands and lakes would continue protecting wetland values such as shade, temperature, and downed wood.

As summarized previously and described in detail in the Aquatic Ecosystems Assessment (U.S. Department of Agriculture 2019a), PACFISH and INFISH Biological Opinion (PIBO) monitoring data, as well as the Nez Perce-Clearwater's own monitoring under the 1987 plans, suggest that this direction achieved the goal of preventing additional degradation at the forest scale, considering all indicators collectively.

Effects common to action alternatives

The Nez Perce-Clearwater Aquatic Ecosystems plan components are part of all five action alternatives and replaces PACFISH and INFISH. Plan components directly related to riparian management are shown in Table 132. The action alternatives would rename and redefine riparian widths, instead of keeping them the same as under the No Action Alternative, replacing riparian habitat conservation areas terminology with riparian management zones (RMZs). As is the case under the No Action Alternative, RMZs are not specifically allocated as a management area in the plan but are instead defined through plan direction. This direction includes a standard that describes the delineation of RMZs and defines their minimum width (FW-STD-RMZ-07). The reason they are not allocated as a management area is because RMZs are intimately linked to water features and to the unique terrain and site characteristics associated with each feature. They can only be accurately determined at the site-specific scale during project analysis.

Table 132. PACFISH/INFISH riparian/channel management standards and guidelines crosswalk with Land Management Plan standards and guidelines.

PACFISH/INFISH	Land Management Plan
RA-3. Apply herbicides, pesticides, and other toxicants, and other chemicals in a manner that does not retard or prevent attainment of Riparian Management Objectives and avoids adverse effects on listed anadromous and inland native fish. RA-5. Locate water drafting sites to avoid adverse effects to inland native fish and instream flows, and in a manner that does not retard or prevent attainment of Riparian Management Objectives.	FW-STD-WTR-03. Portable pump set-ups and fuel containers in riparian management zones shall include appropriate containment and cleanup provisions for fuel spills. FW-STD-WTR-05. When drafting water, pumps shall be screened to prevent capture or harm of fish and aquatic organisms. Pumping sites shall be located away from spawning gravels. To prevent the spread of invasive species, pumps, charged hoses, and drafted water shall not be backflushed or discharged into stream channels, wetlands, or other water bodies. FW-GDL-WTR-04. To avoid adverse effects to spawning and staging fish, their eggs, and embryos, instream activities, and near-stream activities with the potential to disturb spawning fish and directly deliver sediment to spawning habitat, should be implemented in accordance with State of Idaho instream work window guidelines. FW-STD-RMZ-03. Herbicides, pesticides, and other toxicants and chemicals shall only be applied within riparian management zones

PACFISH/INFISH	Land Management Plan
	when the activity does not retard attainment of aquatic and riparian desired conditions. FW-STD-RMZ-07. The Riparian Management Zone definitions in the introduction of section 2.2.2 (Riparian Management Zones) shall be used for all actions and projects. FW-GDL-RMZ-08. To maintain water quality, pumping directly from a stream channel should be avoided if chemical products are to be directly mixed with water being withdrawn. When chemicals are used, pumping should be conducted from a fold-a-tank that is located outside the riparian management zones.
RA-4. Prohibit storage of fuels and other toxicants within Riparian Habitat Conservation Areas. Prohibit refueling within Riparian Habitat Conservation Areas unless there are no other alternatives. Refueling sites within a Riparian Habitat Conservation Area must be approved by the Forest Service or Bureau of Land Management and have an approved spill containment plan.	FW-GDL-WTR-01. To maintain channel forming processes and aquatic habitat, large woody debris should not be cut or removed from stream channels or floodplains unless it threatens public safety or critical infrastructure, such as mid-channel bridge piers. FW-GDL-WTR-04. To avoid adverse effects to spawning and staging fish, their eggs, and embryos, instream activities, and near-stream activities with the potential to disturb spawning fish and directly deliver sediment to spawning habitat, should be implemented in accordance with State of Idaho instream work window guidelines. FW-GDL-RMZ-10. To conserve Pacific lamprey and Western pearlshell mussel populations, individuals should be re-located to an alternative site with suitable habitat prior to de-watering channel work proposed in areas containing habitat for these species.

The riparian management zone (RMZ) minimum width for all intermittent streams would be 100 feet under the action alternatives, instead of varying from 50 to 100 feet, as they do for some sub watersheds under current direction. Landslides and landslide-prone areas remain a Category 4 RMZ, noted as unstable or potentially unstable areas, as shown in Table 133.

Table 133. Minimum width of Riparian Management Zones under the Action Alternatives.

RMZ Category	Minimum width on each side of stream, pond, wetland, or unstable slopes
Category 1 – Fish bearing streams	300 feet
Category 2 – Permanently flowing non-fish bearing streams	150 feet
Category 3 – Constructed reservoirs, ponds, lakes, and wetlands >1 acre	150 feet
Category 4 – Seasonally flowing or intermittent streams, pond, lakes, wetlands < 1 acre, unstable or potentially unstable areas	100 feet

Further clarification is provided for Category 1 RMZs. The area around any stream, whether perennial or not, is considered a Category 1 RMZ if it contains fish at any time of the year and is

300-feet on either side. From the definition, fish-bearing intermittent streams are distinguished from non-fish-bearing intermittent streams by the presence of fish for any duration. Many intermittent streams may be used as spawning and rearing streams, refuge areas during flood events in larger rivers and streams or travel routes for fish emigrating from lakes. In these instances, the guidelines for fish-bearing streams would apply to those sections of the full-extent of intermittent stream used by the fish from the mouth to the upper-most point of fish use.

As described in the Riparian Management Zone section of the Aquatic Ecosystems plan components, there are qualifiers on the total widths of RMZs based on site-specific conditions but as mentioned, these minimum widths are used for analysis at the programmatic level in this Final Environmental Impact Statement.

Riparian management zone (RMZ) direction under all action alternatives was refined through plan components designed to guide appropriate management based upon best available science. Monitoring and research reports over the past 20 years have documented the efficacy of RMZs and their ability to protect the functional attributes needed for riparian and aquatic resources and water quality. Using stream temperature as a response variable, a study in Oregon found no differences in temperature before and after a project using a no-cut buffer as small as 25 feet (Groom et al. 2011). Similarly, a comprehensive study in Oregon and Washington that evaluated various buffer widths found no increases in stream temperature using a 50-foot buffer (Anderson and Poage 2014). The latter study did point out that the efficacy depended on the adjacent disturbance and contrast in forest canopy.

Many researchers suggest that a 100-foot area where trees are retained next to fish-bearing and perennial streams is generally likely sufficient to protect against temperature increase (Anderson and Poage 2014, Reeves, Pickard, and Johnson 2016, Sweeney and Newbold 2014, Witt et al. 2016). Even so, considerations of context and geography are also appropriate. In a discussion of fixed-width riparian buffers, Richardson et al. (2012) state that although these types of protections are administratively simple to implement at the stream reach scale, watershed considerations and location within the catchment provide additional important context.

Riparian management zones on the Nez Perce-Clearwater are classified as not suitable for timber production under these alternatives, based on the determination that a scheduled flow of commercial timber products using a rotation age could not be expected to occur on these lands due to management requirements and desired conditions for other resources. Vegetation management is allowable with restrictions as specified in the Aquatic Ecosystems plan components. Other vegetation management activities are also allowed and are expected to occur to maintain desired conditions for riparian areas or other resources, as described further below. Refer also to the discussion later in this section on effects to riparian areas from timber and vegetation management.

Vegetation management in the RMZ would occur only for the purposes of restoring or enhancing riparian, fish, and aquatic resources (FW-STD-RMZ-01).

FW-STD-RMZ-01 was designed in conjunction with FW-STD-RMZ-04, FW-STD-RMZ-07, FW-GDL-RMZ-01, FW-GDL-RMZ-02 to replace Standard TM-1 in PACFISH and provide clarification of this language in TM-1: “Apply silvicultural practices for Riparian Habitat Conservation Areas to acquire desired vegetation characteristics where needed to attain Riparian Management Objectives. Apply silvicultural practices in a manner that does not retard attainment of Riparian Management Objectives and that avoids adverse effects on listed anadromous and inland native fish.” It does this by including the phrase “vegetation management shall only occur in riparian management zones”, and then specifies where, under what conditions, and for what purposes vegetation management is permitted.

Additionally, any vegetation treatments in riparian management zones would be designed to reflect the composition, structure, and pattern of vegetation consistent with the natural range of variation (NRV), as described in the desired conditions.

Fire is a natural disturbance process that has historically influenced the Nez Perce-Clearwater within watersheds, including riparian areas and forests adjacent to water features. The natural role of fire and other natural disturbances in creating the diversity of successional stages, species compositions, and structures in riparian areas is incorporated into the design of the desired forest and vegetation conditions outlined in the plan (FW-DC-RMZ-01 and 02).

The Aquatic Ecosystems plan components also contain standards and guidelines that are intended to prevent degradation from any harvest that might occur in riparian management zones (RMZs). These components provide more specific direction and clarification beyond what is included in PACFISH and INFISH. They include FW-STD-RMZ-03, where herbicides, pesticides, and other toxicants and chemicals shall only be applied within RMZs when the activity does not retard attainment of aquatic and riparian desired conditions. FW-GDL-RMZ-01 applies to new landings, skidding, staging or decking, and machine burn piling that should be located outside RMZs to minimize effects to riparian and aquatic resources. Where new activities inherently must occur in RMZs, they should be located so that they do not degrade or retard aquatic and riparian desired conditions. FW-GDL-RMZ-02 will reduce the likelihood of sediment input to streams by avoiding new road, trail, and landing construction, including temporary roads, in RMZs. FW-GDL-RMZ-03 directs yarding activities to achieve full suspension over the active channel to prevent damage to stream channels.

Additional components addressing effects from other activities would not lead to different outcomes when compared to PACFISH and INFISH direction and provide enhanced direction and clarification over what is provided in these amendments. To limit impacts from fire suppression activities, RMZs would have limited exposure to fire retardant (FW-GDL-RMZ-04) and new fire facilities would rarely be allowed to be located within these zones (FW-GDL-RMZ-05). These protections carry forward existing protections under the No Action Alternative and provide additional clarification. Fireline construction would be avoided in RMZs, except at stream crossings (FW-GDL-RMZ-06).

For all activities, including and especially those within RMZs, FW-STD-WTR-04 applies. This standard specifically directs that “projects shall restore or not retard attainment of desired conditions.” This standard clarifies the following statement in PACFISH, “Actions that reduce habitat quality, whether existing conditions are better or worse than objective values, are inconsistent with the purpose of this interim direction.” In other words, FW-STD-WTR-04, as part of all action alternatives, carries forward the same expectation from PACFISH, using language consistent with the 2012 Planning Rule and eliminating the word “interim.” In that sense, the expectation that Nez Perce-Clearwater actions will not result in permanent, long-term degradation of aquatic habitat, including RMZs, is the same for all alternatives. Therefore, outcomes from Alternatives W, X, Y, and Z, and the Preferred Alternative would be expected to be indistinguishable from those in the No Action Alternative.

Establishment of the Conservation Watershed Network, along with additional desired conditions and standards, further builds on the restoration concept where habitats are currently degraded, as discussed in greater detail in Effects of Forestwide Direction on Aquatic Habitat.

Aquatic Habitat Environmental Consequences

Effects of Forestwide Direction on Aquatic Habitat

No Action Alternative

For riparian areas and riparian habitat conservation areas, PACFISH amended the 1987 Nez Perce and Clearwater Forest Plans and is unchanged from its original wording in the No Action Alternative. INFISH amended the Clearwater Forest Plan in areas not supporting anadromous fish, which broadly includes the Upper and Lower North Fork Clearwater subbasins above Dworshak Dam and the Palouse River. Both underwent programmatic consultations in 1995 for listed salmon and again in 1998 for listed steelhead and bull trout, and additional requirements in the resulting Biological Opinions legally became part of PACFISH and INFISH and were implemented on the Nez Perce and Clearwater National Forests. Both PACFISH and INFISH and their Biological Opinions reduced the risk to watersheds and riparian and aquatic resources by improving riparian zone protections. They also included over-arching direction for actions that resulted in a reduction in aquatic habitat quality and thus were not consistent with the Biological Opinions. They were intended to arrest additional aquatic habitat degradation until the Nez Perce-Clearwater revised forest plans and replaced PACFISH and INFISH with more site-specific direction.

Of note, the 1998 National Marine Fisheries Service Biological Opinion for steelhead incorporated nine recommendations into the ongoing actions proposed by the U.S. Forest Service and Bureau of Land Management and agreed upon by three regional foresters to avoid a jeopardy determination for continued implementation of land management plans. These recommendations included special management considerations for the Middle Fork Salmon, South Fork Salmon, and Selway Rivers. These river basins are considered to support three stronghold populations of wild steelhead, one of which is the Selway River located on the Nez Perce-Clearwater. These management considerations included enhanced direction for management of timber, roads, fire, and recreation and were intended to minimize risks to these populations beyond measures included in PACFISH. They also emphasized restoration of degraded habitat.

Prior to PACFISH and INFISH, both the Clearwater and Nez Perce Forest Plans contained direction regarding aquatic resources, streams, and fish, particularly regarding potential sediment effects. Direction in the previous Nez Perce Forest Plan for aquatic resources was predicated on the principles of meeting “fish/water quality objectives” at a scale generally smaller than HUC12. Fish and water quality objectives were established based on the beneficial uses in each watershed and species present and ranged from 70 to 100 percent. Additional guidelines related to sediment yield and entry frequency for timber harvest were established based on these objectives. Sediment yield guidelines, entry frequency guidelines, and fishery habitat potential were included. The information and direction related to fish and water quality objectives, sediment yield guidelines, and entry frequency guidelines are contained in Appendix A of the Nez Perce Forest Plan. This guidance is now several decades old and was based upon the best available information at the time, but much of it is now outdated. The plan components in the revised Land Management Plan are based on knowledge gained during those decades under the current plan, updated baseline information, updated scientific information, and policy considerations.

In many cases, the current fishery habitat potential, as it was described in the 1987 Plan, was lower than its water quality objective value. These watersheds were assigned additional direction stating that “timber management can occur in these watersheds, concurrent with improvement efforts, as long as a positive, upward trend in habitat carrying capacity is indicated.” This direction was crafted to address the following forestwide standard: “Meet established fish/water quality objectives for all prescription watersheds as shown in [the Nez Perce Forest Plan] Appendix A." The upward trend direction was intended to allow timber harvest in watersheds not currently meeting their fish and water quality objectives, as long as watershed or stream improvements were also implemented that moved stream conditions towards their objectives.

Some watersheds were assigned a fish and water quality objective that was less than their current fishery habitat potential, thus allowing for a measure of planned degradation in these watersheds. In all cases, sediment yield and entry frequency guidelines varied according to fish and water quality objectives and were intended to function as thresholds providing the maximum increase in sediment yield plus the number of times that increase could occur in a decade that would allow for these objectives to be met.

Thus, the upward trend direction in the 1987 Nez Perce Forest compelled action intended to restore degraded fish habitat if timber harvest was to be pursued in watersheds that did not meet forest plan objectives.

Direction in the Clearwater Forest Plan was in many respects similar to the Nez Perce Forest Plan, as both national forests shared the same issues related to anadromous fish, sediment, and aquatic resources. The Clearwater Forest Plan equivalent to Appendix A of the Nez Perce Forest Plan was Appendix K, in which criteria for management of water resources was defined and assigned to specific watersheds at a scale generally smaller than HUC12. Rather than numeric fish and water quality objectives, this plan assigned one of six categories of water quality objectives, which included Basic, No Effect, High Fishable, Moderate Fishable, Low Fishable, and Minimum Viable. Assignment of watersheds to one of these objectives was based on one of five indicator fish species. Sediment loadings were assigned to each objective.

The Clearwater Forest Plan did not include upward trend direction for any of its watersheds. The Plan and record of decision, however, were challenged in court shortly after signing, and an out-of-court settlement included the following language:

"The Forest Service will proceed only with projects that result in no measurable increase in sediment production in drainages currently not meeting Forest Plan standards. The Forest Service also agrees, as budgets permit, to repair or correct any known sediment sources… Project plans will include a clearly described watershed improvement objective and identify improvement opportunities and realistic expectations offered by the project proposal."

This language is the current management direction.

To assess the effects of the 1987 Forest Plan direction, as amended by PACFISH and INFISH, PACFISH and INFISH Biological Opinion (PIBO) data provides a description of the existing stream conditions compared to reference and an analysis of trend. The data is summarized in Table 122, Table 123, Table 124, Table 125. For existing condition, the data presented indicates that overall stream conditions in managed watersheds on the Nez Perce-Clearwater, when all indicators are considered collectively, are within the range of natural variability. The data suggests that all indicators are better than or not less than residual pool depth, pool percent, and large wood frequency are degraded and less favorable for salmonids when compared against reference subwatersheds. In addition, median substrate size, bank angle, and macroinvertebrate assemblage in managed subwatersheds are indistinguishable from reference, and pool fines are in a more favorable condition than in reference subwatersheds. It should be noted that the term "reference" should not be confused with "undisturbed."

For trend, PIBO data indicates an overall improving trend when data from all sites across the Nez Perce-Clearwater are combined for OE, D50, and large wood frequency. At the subbasin scale, the subbasin with an overall statistically significant improving trend is the Lower Selway for 2019; although in 2016, the Lochsa, Lower Selway, South Fork Clearwater River, and Lower Salmon showed improvement. A statistically significant downward trend is indicated by data from managed sites in the Clearwater and South Fork Clearwater, although current conditions as of 2016 were within the range of reference.

Forest plan monitoring data is available for both the Nez Perce and Clearwater National Forests. For the Nez Perce National Forest, cobble embeddedness was the primary metric monitored, and analysis of the available data suggests that 1987 Forest Plan direction related to upward trend, combined with the PACFISH amendment, did indeed result in improved sediment conditions at the sites where data is available. Most notable among these decreases were sites in Red River and Newsome Creek, which have moratoriums on additional sediment producing activities, such as timber sales, until they recover to desired conditions. PIBO data appears to corroborate these conclusions.

Effects common to all action alternatives

This effects section will focus on three subsections, including indirect consequences of the action alternatives, specific activities likely to occur in the future, and aquatic plan components that are common to all action alternatives.

Aquatic habitat environmental consequences focus on two categories of actions and activities. The first category includes indirect consequences of action alternatives because they would not cause direct effects on the ground. For example, management area designations, establishing riparian management strategies, and selecting plan components are all proposed actions but are programmatic in nature such that they would only have indirect effects later in time. The second category includes specific activities likely to occur in the future that would be guided by the forest plan but are not yet formally proposed. Examples include infrastructure use, vegetation management, mining, recreation, etc. The effects analysis for these activities would occur during future Section 7 consultation after specific project proposals have been developed. Instead of an effects analysis in this document, the appropriate programmatic method for addressing these potential future activities is explaining how future actions guided by the plan might affect listed fish and critical habitat, given the potential land uses, description of desired components, and constraints imposed by standards and guidelines.

The U.S. Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) have identified nine physical or biological features (PBFs) that describe pathways needed to support critical habitat (originally called “primary constituent elements” but officially changed to “physical or biological features” effective March 14th, 2016; 81 FR 7413). PBFs include habitat elements such as spring, seeps, and groundwater; migratory habitats; abundant food base; complex habitats; water temperature; natural hydrograph; water quality and quantity; and low levels of nonnative predators and competition. For this analysis, PBFs for all critical habitats have been aligned via a crosswalk table because they are similarly worded and could be similarly affected by proposed actions (Table 134).

Table 134 Standardized physical or biological features for the designated critical habitat of Bull Trout, Chinook Salmon (both races), and Steelhead.

Number	Bull Trout	Chinook Salmon	Steelhead
1	Springs, seeps, groundwater sources, and subsurface water connectivity (hyporheic flows)	water quality, quantity, temperature	water quality, water quantity
2	Migration habitats	free of artificial obstructions	floodplain connectivity, free of obstructions
3	An abundant food base	food, natural cover,	forage
4	Complex environments/processes that maintain them	cover, shelter, riparian vegetation, natural cover, space	floodplain connectivity, free of obstructions, natural cover
5	Water temperatures ranging from 36 to 59 °F	water quality, quantity, temperature	water quality, water quantity
6	Substrate of sufficient amount, size, and composition	spawning gravel, substrate	water quantity and floodplain connectivity, physical habitat conditions
7	A natural hydrograph	water velocity	water quantity
8	Sufficient water quality and quantity	water quality and quantity	water quality and quantity
9	Sufficiently low levels of occurrence of nonnative fish	no equivalent	no equivalent

Indirect Effects of Action Alternatives

Management area allocations can provide beneficial or adverse effects to listed species' critical habitat and essential fish habitat, depending on whether they increase or decrease recommended wilderness. This affects the number of acres that would be unsuitable for several activity types that otherwise could adversely affect physical or biological features (PBF)(for example, permanent road building) and greatly constrain others (for example, timber production). Refer to MA2-SUIT-RWILD plan components for complete suitability direction for recommended wilderness. The number of proposed wild and scenic rivers varies as well, however, stream and riparian protections would not be compromised because the quarter-mile protection corridor afforded by the National Wild and Scenic Rivers System Act is larger than necessary to protect stream functions such that the proposed riparian management zone (RMZ) distances would offer sufficient protection as determined by PACFISH/INFISH. Furthermore, RMZ plan components provide guidance for management activities to re-establish disturbance patterns in areas where it is lacking to restore riparian processes according to proposed RMZ desired conditions (FW-DC-RMZ-01, 02). PBF 4 would indirectly benefit from alternatives that increase recommended wilderness, and RMZ guidelines that are equally as protective as PACFISH/INFISH protections would contribute to the types of natural processes that provide complex habitat, natural cover, and refugia.

Suitability of motorized and non-motorized access proposals have the potential to adversely affect PBF 6 and the water quality components of PBFs 1 and 8 if lands suitable for motorized use are proposed to increase for both summer and winter. Roads and trails that support motorized use can cause sedimentation and large woody debris issues if not hydrologically disconnected. However, proposed standards and guidelines are expected to mitigate these effects. For example, FW-STD-ARINF-01 says, "Road maintenance and new road construction shall be designed to minimize adverse effects to threatened, endangered, proposed, or candidate aquatic species and their habitat," and FW-GDL-ARREC-02 says, "To reduce potential adverse effects to water quality and aquatic resources, construction of new facilities or infrastructure within floodplains should be avoided. Where new activities inherently must occur in riparian management zones (for example, at road and trail stream crossings, boat ramps, or docks), they should be located and designed to minimize adverse effects to floodplains and other riparian-dependent resource conditions (for example, within geologically stable areas and avoiding major spawning areas)." These standards and guidelines would be expected to ensure that if adverse effects to PBFs were to occur in the future as the result of these motorized access suitability proposals, they would be minor and not lead to adverse modification or hinder recovery to conditions described by desired conditions.

Aquatic and riparian management strategies in the proposed forest plan would be beneficial for critical or essential habitat as several riparian management zone (RMZ) and Conservation Watershed Network (CWN) plan components were specifically designed to maintain the intent of PACFISH/INFISH direction (for example, FW-RMZ-STD-07; Appendix E), the same direction that was largely responsible for passive restoration and upward trend in habitat conditions documented by the PACFISH and INFISH Biological Opinion (PIBO) program (Roper 2020). Unlike the focus on passive restoration under the 1987 Forest Plan, the revised forest plan includes components that also emphasize active restoration. For example, FW-OBJ-RMZ-01 says: "Improve 300 to 700 acres of riparian habitat every 5 years, through improvements that are intended to meet desired conditions for riparian management zones, such as road obliteration, riparian planting, hardwood restoration, post assisted log structures, beaver dam analogs, and reconnecting floodplains by removing road prisms or berms." This increased capacity for active restoration has the potential to have long-term beneficial effects to all physical or biological features (PBFs). Identifying inner and outer zones of RMZs that clearly allow for active restoration to occur where desired conditions are not currently being met as opposed to PACFISH and INFISH that was often interpreted as "exclusion zones" or areas that were not readily available for active management.

Indirect effects of alternatives such as the monitoring program, potential management approaches, and other plan content would also be beneficial for critical or essential habitat as these elements are designed to facilitate implementation of the new forest plan. Because the net effect of most other proposed actions as described above are beneficial, proposals to evaluate progress towards meeting desired conditions and engage in partnerships, establish priority watersheds, etc. would likewise have a variety of effects on all PBFs. There are several relevant roles of plan components, which include limiting adverse effects of forest management, and promoting effective restoration and mitigation. When considering the plan as a whole, some plan components have negative effects on aquatics, that are at least partly reduced by potential management approaches, and some components such as those promoting restoration will have beneficial effects.

One of the assumptions of the PIBO monitoring is that the selected stream reaches withing an ecoregion are representative of conditions within that ecoregion. The large-scale sampling design has been shown to be statistically robust and is intended to provide accurate monitoring of trends without having to sample every single stream or stream reach. In addition, some of the bull trout core areas are primarily in Management Area 1 and would not be likely to exhibit downward trends due to active forest management, as none occurs there. Where management does occur, it is guided by plan components that require the Forest Service's best management practices (BMPs) to be used. The BMPs are built upon decades of monitoring to ensure that management does not have deleterious effects on critical habitat.

The net effect of proposed plan components is expected to be primarily beneficial in the long term for critical or essential habitat for the reasons stated above. The primary reason for this is the inclusion of desired conditions that identify what future projects would be designed to achieve. For example, projects in watersheds that contain designated critical habitat would have to "contribute to and enhance the conservation of aquatic species of conservation concern and recovery of threatened or endangered fish species" (FW-DC-CWN-01); "provide habitat that supports robust native fish populations, which are able to expand to and recolonize adjacent unoccupied habitats" (FW-DC-CWN-02); and ensure "critical habitat components (primary biological features) provide the ecological conditions necessary to achieve species recovery. Spawning, rearing, and migratory habitat are widely available and inhabited. Listed aquatic species have access to historic habitat and appropriate life history strategies (for example, bull trout resident, fluvial, adfluvial; and salmonid anadromy) are supported" (FW-DC-WTR-10). It is important to note that while some plan components could temporarily have adverse effects to critical habitat (for example, FW-OBJ-TBR-01: Offer 190-210 million board feet timber per year), those components would have to be implemented in a way that does not compromise the above-mentioned desired conditions for critical habitat. The following section provides additional information on how proposed plan components would guide the management of future activities.

Management of Activities Likely to Occur

This section describes activities likely to occur that would be guided by proposed forest plan components.

Infrastructure

The revised plan carries forward components and the intent of PACFISH and INFISH with some modification. For example, under the 2012 Planning Rule, Standards and Guides are not allowed to compel action, therefore the verbiage is changed for some components in the revised plan. In the place of those components, the Revised Plan has a far-reaching desired condition FW-DC-ARINF-01. It states, "The transportation system has minimal impacts on aquatic and riparian conditions through reduced hydrologic connectivity of roads to streams, lower sediment delivery to streams, reduced road impact to floodplains, and improved aquatic organism passage, where transportation infrastructure affects these features." Under the revised plan, all road planning and activities must be designed to move the road system towards this desired condition. With addition of this desired condition, specific standards and guidelines that compel action under PACFISH and INFISH are not carried forward. An example would be PACFISH RF-2 c.2. which required developing a Road Management Objective for every road segment.

In addition to desired conditions, standards, guides, and goals, the revised plan has objectives. In the Forest Service Directives, objectives under the 2012 Planning Rule are described as, "A concise, measurable, and time-specific statement of a desired rate of progress toward a desired condition or conditions. Objectives should be based on reasonably foreseeable budgets." The Conservation Watershed section of the revised plan has objectives for assessment of roads, regardless of maintenance level, that are most likely to be negatively impairing aquatic conditions and road storm-proofing (discussed below).

The revised plan carries components forward that restrict actions associated with existing road management that could otherwise retard attainment of aquatic restoration. The revised plan also contains components that restrict placement and construction of new roads such that the road network "has minimal impacts on aquatic and riparian conditions" (FW-DC-ARINF-01), and "road maintenance and new road construction shall be designed to minimize adverse effects" to listed species and their habitat (FW-STD-ARINF-01). Under the existing plans, the national forests have decommissioned 19 percent of the specified road system since PACFISH and INFISH in 1995.

Desired Conditions in the Revised Plan state that the road system is needed to "serve land management and public needs and purposes" (FW-DC-INF-01). The component FW-DC-INF-02 states, "Roads not needed to serve management and public needs and purposes are absent." When considered together, these two desired conditions acknowledge the desire of the public retain access to National Forest System lands while at the same time, roads that are not needed for access or management will be reduced during future projects.

To balance social, economic, and ecologic sustainability, and to support rural communities, guideline FW-GDL-ES-01 requires the Nez Perce-Clearwater to retain public access to areas that currently have open motorized access, in the summer or winter. When a route is identified as adversely affecting aquatic resources, the component guides maintenance or rerouting to be considered as alternatives to closing the route. If the route must be closed, the guideline states an alternative route should be provided. This guideline does not prohibit road closures per se, but it does provide a framework of alternatives that should be followed before implementing a closure, and it recognizes the importance of ecosystem services to the public. While this guideline does require the Forest Service to continue to provide ecosystem services that national forest visitors and rural communities expect, it does not absolve the national forest from the entirety of the rest of the plan nor does this plan component supersede any other. Instead, this guideline works in concert with other plan components to describe potential adverse impacts to aquatic resources and describe conditions that this ecosystem services plan component must work within. The scenario of multiple plan components working together to address problems in ways that promote the landscape toward desired conditions precludes any one plan component being a limiting factor for a resource. For example, specifically, FW-OBJ-WTR-02 aims to "enhance or restore" 50 – 100 miles of stream in unconfined channels every five years through means including streamside road decommissioning and floodplain restoration and FW-OBJ-INF-01 aims to "Complete 600 miles of road work, such as reconstruction; re-routing; road improvements; decommissioning; or placing roads in intermittent stored service, every 5 years. Priorities shall include reducing effects on desired aquatic and riparian conditions from chronic sediment delivery or potential future road prism failures, including previously decommissioned roads where drainage features have failed." Additional plan components, such as FW-DC-INF-02 that states "Roads not needed to serve management and public needs and purposes are absent" provide the pretext for removing system roads that are not needed for management or public purposes during travel planning. Additionally, FW-DC-INF-02 applies to non-system roads and routes that are on the landscape but not part of the transportation system. Removal of these unneeded roads from the landscape, particularly those near streams, can significantly reduce sediment production (Madej 2001).

Some roads are deemed important for future, but not current, use and are placed in storage. Forest Service roads that are not in use for periods of one year or more are Operational Maintenance Level 1 roads per the Forest Service Handbook (FSH 7709.59 62.32). Treatment for storing roads ranges from no ground disturbance activities to removing drainage structures. Site specific analysis is used to determine what treatment, or combination of treatments, would be appropriate for specific locations. Stored roads with a high potential to impact natural resources may warrant more intensive treatments, such as removal of culverts or prism modification. It may be appropriate to store roads that have minimal potential to impact natural resources with less intensive treatments, such as blocking the road entrance, installing waterbars, and seeding disturbed areas. Selecting appropriate treatments for road storage requires consideration of existing and future use, potential resource impacts, length of time the road is in storage, cost to implement treatments, and available funding. A more detailed description of the road storage and decommissioning decision making, and procedures used by the Forest Service can be found in the publication Guidelines for Storing and

Decommissioning Roads (USDA 2018). A more detailed description of the conditions associated with storage roads on the Nez Perce-Clearwater National Forest (including photographic examples), is provided under the Travel Management heading under Activities Likely to Occur Under the Land Management Plan heading in this document. The ground disturbance associated with decommissioning a road that is already in a hydrologically stable condition can sometimes create more initial sediment input to streams than leaving the same road in storage, and although both types of treatments can lead to similar aboveground properties, belowground properties and ecosystem processes can be altered (Lloyd et al. 2013). Effects of road treatments and road status are highly dependent upon many factors such as slope, soil type, and road location. Thus, decisions concerning appropriate road treatments are best evaluated at a site-specific project level. In the process of doing those evaluations, the revised forest plan will guide efforts through plan components that are intended to keep the focus of all management activities on the attainment of desired conditions.

Aquatic components in the proposed Revised Plan support a naturally functioning sediment regime that supplies of the "types, quantities, and rates" of sediment that "support the natural…substrate composition" for the benefit of listed species and their habitat (FW-DC-WTR-06, FW-STD-ARINF-01). Within the Conservation Watershed Network (CWN), road projects or projects with road-related components will be designed to support and "not retard" processes of natural habitat creation, maintenance, and recovery (FW-STD-CWN-01), in part by reducing the hydrologic connectivity of the road network (FW-STD-ARINF-07). Storm proofing, which is a non-recuring treatment to existing roads to reduce the potential for resource impacts from road feature failure, will target 15 percent of the road mileage every five years in the CWN (FW-OBJ-CWN-02). As indicated in Appendix 4 of the Revised Plan, section 1.11.3 Road Storm Proofing, potential management approaches include using road storm proofing techniques following Keller and Ketcheson (2015) or similar, and the U.S. Forest Service Transportation Resiliency Guidebook - Addressing Climate Change Impacts on U.S. Forest Service Transportation Assets (U.S. Department of Transportation 2018). As culverts are replaced either for road maintenance purposes or as a restoration component of larger projects, or in the event a new road is constructed across a stream, new stream crossing structures will allow for aquatic organism passage where desirable and feasible (FW-GDL-ARINF-11; PBF 2).

Site specific improvements can be made to reduce effects, particularly those associated with streamside roads and stream crossings. While adverse effects to stream habitats are likely to occur due to the road network, guidelines in the plan aim to reduce those risks to the extent feasible and utilize a proactive approach to road design, construction, and maintenance (GDL-ARINF-01-07, 09-11). Additionally, project-specific best management practices (BMPs), including both federal and state BMPs, shall be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet water quality desired conditions, and to protect beneficial uses (FW-STD-WTR-02). Best management practices for road-related operations can be found in the Soil and Water Conservation Practices handbook (U.S. Department of Agriculture 1988a), the Idaho Forestry Best Management Practices Field Guide: Using BMPs to Protect Water Quality (University of Idaho Extension Office 2015), and the National Best Management Practices for Water Quality Management on National Forest System Lands Technical Guide (U.S. Department of Agriculture 2012b). Shaping road surfaces to drain as designed, constructing or reconstructing drainage control structures as needed, ensuring ditches and culverts are clean and functioning, not permitting side casting of maintenance-generated debris within the riparian management zones (RMZs), and designing stream crossing structures to have sufficient capacity to convey the design flow without appreciably altering streamflow characteristics are a few examples of BMPs. The U.S. Forest Service's San Dimas Technology and Development Center completed a literature synthesis describing the effectiveness of

BMPs that have application to forest roads (Edwards et al. 2016). The report concluded that based on the results of most of the studies, the case could be made that most BMPs result in some level of effectiveness in terms of reduced sediment generation or transport, although wide ranges of BMP effectiveness were reported in many of the studies. Forest roads designed to minimize erosion, as proposed, can result in considerably less sediment mobilization (Ketcheson and Megahan 1996). The plan thus aims to reduce baseline, non-project specific, and project-specific impacts to streams related to roads and therefore "not retard" natural rates of recovery. This would likely be accomplished through a combination of mechanisms to include (1) forest road maintenance, (2) integrated projects with road mitigation or improvement elements, and (3) as direct mitigation for timber sales. This is in the context of the potential for increased timber harvest in the future as the infrastructure section of the Final Environmental Impact Statement estimated that the number of log truck trips on forest roads could increase. Currently, about 1,200 miles of Nez Perce-Clearwater roads are maintained each year. Objectives in the revised plan identify a goal of 1,400 miles of road maintenance per year (FW-OBJ-INF-02). Gravel surface replacement is currently accomplished on the Nez Perce-Clearwater using timber harvest receipts and approximately 25 percent of forest road maintenance is performed by timber purchasers; it is expected that the amount of road maintenance performed by timber purchases would remain commensurate under the new plan (that is, if timber sales increase, the amount of road maintenance they perform would also increase). Revised plan components designed to guide management of infrastructure near streams are coded as ARINF (Aquatics and Riparian Infrastructure).

Vegetation Management

The revised plan authorizes and guides vegetation management, including commercial timber sales and non-commercial vegetation management activities. In the revised plan, proposed riparian management zones (RMZs) remain the same as riparian habitat conservation areas (RHCAs) in PACFISH and INFISH, or are slightly wider, as non-priority watershed intermittent streams have an increase of 50 feet. Distinctions have been made in the revised plan to clearly identify what kinds of actions are appropriate and inappropriate within the RMZ (FW-STD-RMZ-07).

Along Category 1 fish-bearing streams, the RMZ consists of, "the stream and the area on each side of the stream extending from the edges of the active stream channel to the top of the inner gorge; or to the outer edges of the 100-year floodplain; or to the outer edges of riparian vegetation; or to a distance equal to the height of two site-potential trees; or 300 feet slope distance equaling 600 feet total, including both sides of the stream channel, whichever is greatest." Riparian management zones begin at 150 feet on non-fish-bearing perennial streams and 100 feet on seasonally intermittent streams. See riparian management zone definitions in the plan for more specifics including lakes and ponds. Seasonally intermittent streams used by fish would be treated as fish-bearing streams. Desired conditions of the revised plan include RMZs that reflect native plant communities and support the landscape processes that create and maintain cool, clean, complex, and connected instream habitat (FW-DC-RMZ-01/02, FW-DC-TE-05). Timber harvest would not occur on particularly vulnerable ground (FW-STD-TBR-02) or using means or in locations where impacts might outweigh economic returns (FW-STD-TBR-04). Guidelines aim to prevent adverse impacts to streams by avoiding logging-related activities in RMZs and yarding timber over streams rather than through them (FW-GDL-RMZ-02/03). Objectives target activities to steer RMZs closer to reference conditions (FW-OBJ-TE-01, FW-OBJ-RMZ-01).

Per FW-STD-RMZ-01, limited timber harvest could occur within the first site potential tree height distance from streams if needed to restore or enhance aquatic and riparian resources. Trees harvested must be left on site or used for aquatic restoration (FW-STD-RMZ-01). While trees cut could potentially interact with other processes, especially stream temperature, desired condition FW-DC-WTR-05 guides projects to meet state beneficial needs, which would limit harvest if tree cutting increased thermal input to the point where beneficial uses could not be met. Other typical examples of allowable treatment in the inner RMZ include hand thinning to underplant native hardwoods species which would move an RMZ closer to reference conditions if hardwoods were under-represented in that sub-watershed. Vegetation management could occur within the second site potential tree height distance provided that the "functions" relative to stream habitat of the outer RMZ were retained (FW-STD-RMZ-01). At least 10 percent of the trees harvested from the second site potential tree height area would be used for aquatic restoration on the Nez Perce-Clearwater (FW-OBJ-RMZ-02).

Vegetation management within riparian areas would largely be addressed by riparian management zone (RMZ) plan components designed to support two desired conditions: "RMZs reflect a natural composition of native flora and fauna and a distribution of physical, chemical, and biological conditions as compared to reference conditions. The species composition and structural diversity of native plant communities in riparian management zones provide adequate summer and winter thermal regulation, nutrient filtering, appropriate rates of surface erosion, bank erosion, and channel migration. Nutrients, large woody debris, and fine particulate organic matter are supplied in amounts and distributions sufficient to sustain physical complexity and stability" (FW-DC-RMZ-01); and "RMZs feature key riparian processes and conditions that function consistent with local disturbance regimes, including slope stability and associated vegetative root strength, wood delivery to streams and within the RMZs, input of leaf and organic matter to aquatic and terrestrial systems, solar shading, microclimate, and water quality" (FW-DC-RMZ-02). The revised forest plan also contains two objectives, seven standards, and ten guidelines (Appendix B). Many of the aquatic protections established by PACFISH and INFISH are continued by RMZ plan components (Appendix E), most notably of which is FW-STD-RMZ-07 that translates riparian habitat conservation area (RHCA) stream buffers into inner and outer RMZ management zones.

Proposed vegetation management could occur on approximately varying acres annually, offering various levels of timber production (FW-OBJ-TBR-02). Minimization of the potential risk to water resources will rely on the effectiveness of RMZs that work well for most stream functions, while timber harvest openings outside RMZs may more closely resemble the effect of natural disturbances on hydrologic and sediment delivery regimes due to the desired condition described above and several other components that address hydrologic effects. Additionally, project-specific best management practices (BMPs), including both federal and state BMPs, shall be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet water quality desired conditions, and to protect beneficial uses (FW-STD-WTR-02). Best management practices for vegetation management related operations can be found in the Soil and Water Conservation Practices handbook (U.S. Department of Agriculture 1988a), the Idaho Forestry Best Management Practices Field Guide: Using BMPs to Protect Water Quality (University of Idaho Extension Office 2015), and the National Best Management Practices for Water Quality Management on National Forest System Lands Technical Guide (U.S. Department of Agriculture 2012b). Designing mechanical vegetation treatment prescriptions to limit site disturbance, soil exposure, and displacement; locating landings, skid trails, and slash piles in suitable sites to avoid, minimize, or mitigate potential for erosion and sediment delivery to nearby waterbodies; and applying soil protective cover on disturbed areas to prevent accelerated erosion are a few examples of BMPs.

Regarding sediment delivery related to peak flow, a recent study has been published to help disentangle increasing peak flows from increasing sediment delivery. Safeeq et al. (2020) found that increased amounts of sediment had more to do with disturbance related to vegetation management that did not leave buffer strips. Restricting activities that bare soils next to streams may be more important than increases in peak flow when considering sediment delivery.

Landscape analysis for the revised plan found a forestwide average disturbance patch size of 350 acres. Plan components focus forest management at the broad potential vegetation type scale. Average patch size varies by broad potential vegetation type with mean averages between 61 to 122 acres. Across broad potential vegetation types, patch sizes range between 25 and 2,680 acres in size. Desired conditions for target average patch size vary by broad potential vegetation type as detailed in Appendix 4 of the revised plan – potential management approaches with the smallest patches associated with the warm dry potential vegetation type (PVT) and the largest patches associated with the cool moist PVT. The revised plan details standards for exceptions which allow the maximum forest opening size to increase from 40 to 207 acres (FW-STD-TBR-06) as described in 36 CFR 219.11 (d)(4)(i). The rationale for using these exceptions at a project level must include restoring ecological conditions or resiliency—for example, restoring a fire regime when currently departed, or moving towards a condition within the natural range of variation (NRV). This standard applies to forest openings created through mechanical harvest operations only and does not apply to openings created through prescribed fire. It is expected that very few proposed openings created by regeneration harvest would reach 207 acres in size due to both target patch sizes for broad PVT groups and limitations of landscape topology which typically constrain opening size. Currently, the average patch size created by even age regeneration harvest on the national forest is 22 acres, and 90 percent of all openings that exceed 40 acres are less than 125 acres. That is because factors such as slope, elevation, aspect, location of riparian areas, etc. generally preclude the existence of large heterogenous timber stands that would all require a uniform silvicultural prescription (that is, given the patchy nature of landscapes in the action area, it is fairly rare to find a treatment area at the scale of 207 acres that would represent a consistent stand for which a single silviculture prescription could be applied). Increasing the average patch size above 22 acres is important ecologically to reduce the amount of edge effects, to allow larger stands of mature forest in the future and to give larger patches for wildlife that require them. Openings larger than 125 acres are unlikely to become more common than they currently are due to the topological constraints that currently limit opening size. Larger openings to be more consistent with the NRV would necessarily be created by wildland fire rather than through timber harvest. This maximum patch size standard approximates the average patch size of disturbance events occurring within the NRV on the national forests such that hydrologic regimes would more closely resemble natural patterns by increasing the size of openings. Because there is a great deal of uncertainty regarding effects to streamflow in particular, a management approach related to plan component FW-DC-WTR-07 was developed that can guide development of an adequate and standardized assessment of potential effects on water yield and peak flows associated with project activities and natural disturbances to provide a consistent approach to determine water yield associated with amount of area harvested. This management approach provides project level planning guidance focused on mitigating potential effects of forest openings.

Managed Wildfire and Prescribed Fire

As fire is the key natural disturbance on the Nez Perce-Clearwater, prescribed fire may be authorized in riparian management zones (RMZs), provided “aquatic and riparian-associated resources are maintained” (FW-STD-RMZ-01). Proposed guidelines seek to minimize adverse impacts to streams during management activities related to fire. FW-GDL-WTR-07 protects RMZs by limiting where and how fireline can be constructed in RMZs so that sediment delivery to waterbodies is minimized and capture of overland flow is limited. Regarding direct ignition of low intensity prescribed fire in RMZs, FW-STD-RMZ-06 states the activity will only be allowed when, “direct ignition within the riparian management zone will not retard attaining water, aquatic, and riparian desired conditions;" and "direct ignition within the riparian management zone maintains or enhances existing stream conditions and effects to threatened or endangered species and their designated critical habitat are considered."

Salvage is unlikely to occur anywhere in RMZs unless it can be shown that aquatic and riparian resources can be maintained and not retarded (FW-STD-RMZ-01). Numerous other guidelines pulled forward from PACFISH and INFISH protect the riparian area from the actions pursued to manage wildfires. FW-GDL-RMZ-04 guides aerial retardant use to avoid application in mapped aerial retardant avoidance areas for the protection of RMZs; FW-GDL-RMZ-05 guides incident bases, staging areas, etc. to be placed outside of RMZs or take mitigation actions if no alternative exists; FW-GDL-RMZ-06 guides machine line to be constructed outside RMZs, and if it must occur through RMZs, it should cross perpendicularly; FW-GDL-RMZ-07 guides restoration of any fire suppression activity that could deliver sediment to streams; and FW-GDL-RMZ-08 guides suppression activities to avoid pumping water directly from a stream.

Allowing naturally ignited fires to play their ecological role, particularly in wilderness areas and designated roadless areas, will produce long-term beneficial effects to aquatic habitat and aquatic species (FW-DC-FIRE-01, FW-OBJ-FIRE-03). Jakober (2002), Rieman et al. (1997) documented increased abundance of fish after fires, even in reaches where the fire had resulted in the local extirpation of fish. (Sestrich et al. 2011) documented a decline in non-native brook trout over time and rapid recovery of native westslope cutthroat trout in severely burned areas in the Bitterroot River, indicating fire may have shifted the competitive advantage in the favor of the native species. At a landscape scale, suppressing fire and reducing its natural effects poses a greater risk to long-term aquatic process and function than the effects of wildfire. Prescribed fire and ecologically beneficial wildfire will promote physical or biological features (PBFs) 3, 4, 6, and 5 by allowing the natural disturbance regime to fuel the stream habitat process that evolved within it.

Wildland fire in riparian areas can help stands move towards reference conditions when it removes excessive fuel loads that otherwise would not have accumulated without fire suppression. Wildland fire, be it prescribed or naturally ignited, can adversely affect stream habitats in its immediate aftermath. It is the natural driver of disturbance on the Nez Perce-Clearwater and thus is integral to the landscape processes that create and maintain instream habitat. Proposed riparian management zones (RMZs), nearly identical to riparian habitat conservation areas (RHCAs), would continue to help create and maintain complex habitat (PBFs 3, 4, 6). It is likely that the proposed RMZs would help keep streams cool (PBFs 2, 5, 8). RMZs provide for clean habitat by filtering overland sediment transport and protecting streambank integrity, two processes that maintain natural sediment routing (PBFs 3, 4, 6, 8). Higher water yields or other changes in the hydrograph could adversely affect PBF 7, but this does not necessarily correlate to increased sediment yield (PBF 6).

Mining

According to the Designated Wild and Scenic Rivers section of the Final Environmental Impact Statement, while "potential for locatable minerals does exist" in the designated portions of the Middle Fork Clearwater River (including the Lochsa and Selway rivers), "there are no valid existing rights, therefore no potential for mining operations" within those corridors. Many of the rest of the streams on the national forests are, however, eligible for mining, provided the noted requirements are met.

To protect riparian and instream habitat, the Nez Perce-Clearwater proposes standards and guidelines that include the requirement of a reclamation plan and a reclamation bond for mining activities in

RMZs (FW-STD-AREM-01); limiting mine waste in RMZs (FW-STD-AREM-02); limiting mineral operation in RMZs unless strict adherence to guidance is followed (FW-GDL-AREM-01/02); controlling water flow paths to maintain water quality and to prevent biological, chemical, or industrial pollutants from being delivered to water bodies (FW-GDL-AREM-03); and requiring the inclusion of best management practices into plans of operations (FW-GDL-AREM-04). Best management practices for mining operations can be found in the Idaho Administrative Code IDAPA 20.03.01, the Manual of Best Management Practices for the Mining Industry in Idaho (Idaho Department of Lands 1992), Forest Service Soil and Water Conservation Practices (U.S. Department of Agriculture 1988a), and the National Best Management Practices for Water Quality Management on National Forest System Lands Technical Guide (U.S. Department of Agriculture 2012b) such as adhering to instream work windows, not discharging wastewater to streams, keeping disturbed areas to a minimum at any given time through concurrent reclamation; and seeding disturbed soil after completion. Lands impacted by mining shall be returned to a pre-disturbance topographical state (FW-STD-EM-01). Some proposed potential management approaches related to general recreation may apply to mining operations in riparian management zones (RMZs), including those related to camps and sanitation in RMZs, for example, see Appendix 4 of the Revised Plan, section 1.16.2 Developed and Dispersed Sites.

Mining will likely adversely affect listed fish and critical habitat, as the techniques used, including suction dredging or placer mining, interrupt natural stream maintaining processes. Physical or biological features (PBFs) sensitive to sediment deposition (2, 4, 6, and 8) could continue to be affected by mining, though monitoring suggested the magnitude of this means of disturbance has been minor in the recent era. The Forest Service has only limited authority to regulate mining, particularly for locatable minerals, and therefore some, even foreseeable impacts would be beyond the purview of the Nez Perce-Clearwater. Minerals activities that are ground disturbing and that use equipment require a plan of operation be submitted for approval. Section 7 consultation would occur on each of these actions that are likely to occur over the life of the plan. It is not possible to predict when and where plans of operation would be submitted, or the potential environmental impacts of these operations at the national forest scale. Thus, the plan components listed above are put in place to ensure minimum requirements are met while relying on project level site specific analysis and consultation to determine potential adverse effects from specific proposed actions.

Currently there are no leasable minerals activities on the Nez Perce-Clearwater. Saleable mineral materials are made available by the national forest. Permitting removal of these materials, unlike locatable minerals, is a discretionary action. Plan components FW-STD-AREM-01, FW-STD-AREM-03, FW-GDL-AREM-01 and FW-GDL-AREM-04 would apply. The limited discretion provision in FW-GDL-AREM-01 would not apply to leasable or saleable materials, thus, should project level site specific analysis find that an action would retard attainment of aquatic and riparian desired conditions, that action would not be allowable under the plan and the project could not go forward.

According to the Designated Wild and Scenic Rivers section, while “potential for locatable minerals does exist” in the designated portions of the Middle Fork Clearwater River (including the Lochsa and Selway rivers), “there are no valid existing rights, therefore no potential for mining operations” within those corridors. Much of the rest of the streams on the Nez Perce-Clearwater are eligible for mining, provided the noted requirements are met.

Livestock Grazing

About 15 percent of the land area of the Nez Perce-Clearwater is within active livestock grazing allotments. All permitted livestock grazing is for cattle, as the one sheep allotment was vacated in 2007. In fiscal year 2020, 4,590 cow and calf pairs were permitted to graze the national forests at various times of the year, but largely from June 1st until September 30th, for a total of 29,861 animal unit months. Table 136 summarizes active allotment acres, livestock numbers, and animal unit months by grazing allotment by subbasin. Beginning May 2024, the Cedar Allotment will become vacant, and the Musselshell Allotment will be administratively closed. Federally listed fish occupy streams within or adjacent to 24 out of 36 active allotments, approximately 67 percent of the allotments (Table 135).

Table 135. Livestock grazing statistics for Nez Perce-Clearwater lands

Grazing Information	Number
Permitted Cattle Numbers[1]	4,590
Permitted Cattle Animal Unit Months Term (Active Allotments)	29,861
Grazing Permittees (Permit Entities)	34
Active Allotments	36
Active Allotment Acres	612,766
Vacant Allotments	9

[1] One cattle number is equal to 1 cow/calf pair or 1 steer or 1 bull; calves greater than 6 months old are counted as cattle

Data Source: Forest Service INFRA database, 2020; Nez Perce-Clearwater geographical information system data

Direction in the current Forest Plan as modified by PACFISH and INFISH has standards and guidelines that protect or minimize effects to listed fish from livestock grazing include modifying grazing practices, locating new facilities outside of riparian habitat conservation areas (RHCAs), relocating or closing facilities, and limiting livestock handling efforts (PACFISH/INFISH GM-1, 2, and 3). Components, such as FW-STD-ARGRZ-01, FW-STD-ARGRZ-02, FW-GDL-ARGRZ-02, FW-GDL-ARGRZ-03 in the proposed action mostly carry forward and expand upon current standards and guidelines.

Streams with lower gradients (primarily less than 3 percent) are the most sensitive to grazing impacts (Rosgen 1996). Proposed guideline FW-GDL-ARGRZ-01 establishes minimum end of season stubble heights of 4 to 6 inches along the greenline for low gradient streams. Alternative use and disturbance indicators and values may be used if they are based on site capability, relevant science, monitoring data, and meet the purpose of this guideline. Stubble height is a meaningful and relatively easily determined metric related to riparian vegetation and has been found to correlate with instream habitat quality (Roper 2020), and has been widely utilized as an end-of-season monitoring indicator (USDA Forest Service, 2022). End of season stubble height (greenline vegetation height) has been shown to be a good indicator of two primary factors: 1) the effect of grazing on the physiological health of herbaceous, hydrophytic plants, and 2) the ability of the vegetation to provide streambank protection and bank building function. Stubble height criteria should be used where streambank stability is dependent upon herbaceous plants. Clary and Webster (1990) recommended that in the Intermountain West, a minimum stubble height of approximately 4 to 6 inches should remain at the end of the grazing season to maintain plant vigor and provide for bank protection and for sediments to be deposited. However, 7.5 to 8 inch stubble height was the optimal length to retain sediment deposits (Thornton et al. 1997, Abt et al. 1994). Similarly, Clary and Leininger (2000) indicated that 6 to 8 inch stubble height would be necessary to protect willow and vulnerable streambanks. Clary (1999) found that 4 inches protected most of the stream attributes while 5.6 inches was needed to protect all stream attributes. Higher average stubble height at the end of season is more likely to provide plants with enough growth during the season to retain vigor in the following season (Clary 1995, Boyd and Svejcar 2012). While height at the end of the growing season still needs more study, some have found positive relationships between higher stubble height at the end of the season and stream habitat conditions (Goss 2013).

Table 383 displays the current stubble height objectives directed in annual operating instructions by allotment as established by specific allotment National Environmental Policy Act (NEPA) or allotment management plans. Of the 36 active allotments, 33 allotments have stubble height objectives between 4 and 6 inches. Three allotments have a stubble height objective of 65 percent utilization. These allotment specific stubble height objectives would be retained until new objectives are established through site specific NEPA, as guided by FW-GDL-ARGRZ-01.

As shown in Table 137 there are approximately 416 miles of streams of low gradient streams (based on average of 3 percent gradient) that occur within active allotments, about 15 percent of the total stream miles within active livestock grazing allotments.

Table 137. Number of stream miles less than and greater than three percent gradient by allotment

Allotment Name	Stream Miles with Gradient Less Than 3 Percent	Stream Miles with Gradient Greater Than 3 Percent

[3]Musselshell Allotment will be administratively closed in May 2024

Twenty of 36 active livestock grazing allotments are located within watersheds included in the Conservation Watershed Network (CWN) Table 136table 138. In addition to standards and guidelines limiting activities that could cause damage to the riparian area, the "do not retard" clause in FW-STD-CWN-01 also applies. This standard is very similar to existing PACFISH standard GM1, both of which require modification of grazing practices which retards or adversely affect listed anadromous fish.

Proposed standard FW-STD-ARGR-03 states during livestock grazing authorizations, re-authorizations, or updates to annual operating instructions, measures should be included to prevent livestock trampling of fish redds of federally listed fish and species of conservation concern. This standard is a partial refinement of grazing standards in PACFISH and INFISH. As shown in Table 138, federally listed fish occur in 24 out of 36 allotments, approximately 67 percent of allotments. This standard has been implemented on the Nez Perce-Clearwater for federally listed fish species since consultation with the U.S. Fish and Wildlife Service and National Oceanic and Atmospheric Administration (NOAA) Fisheries Service in 1999 and 2000. Mitigation measures have been identified and implemented to protect salmon and steelhead redds from livestock trampling according to the agreements in the Forest Service Biological Assessments and concurrence documents from NOAA Fisheries Service. Annual operating instructions for those allotments containing streams with federally listed species provide specific direction and mitigation measures for protection of redds. These measures include identifying redd locations through redd surveys by Forest Service fisheries biologists. If fish redds are identified, mitigation measures, such as changing the date for livestock entry into a pasture containing active spawning, installing temporary or permanent fencing of identified redds or areas of redd concentrations, or use of herding by the grazing permittee to keep cattle away from spawning areas would be implemented. This standard would be applied throughout the life of the plan to the same degree as was applied at the time of consultation with NOAA Fisheries Service. Implementation of proposed plan direction would continue to move resource conditions within allotments toward desired conditions.

[1]Allotment located within a Conservation Watershed Network (CWN)

[2]Cedar Allotment will become vacant in May 2024

[3]Musselshell Allotment will be administratively closed in May 2024

Data Source: Fish distribution spatial data was obtained from Pacific States Marine Fisheries Commission (PSMFC) Stream Net website, http://www.streamnet.org, version 01/31/2019.

The revised plan updates PACFISH and INFISH components and adds additional components to address site-specific adverse effects that could occur. Additionally, project-specific best management practices (BMPs), including both federal and state BMPs, shall be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet water quality desired conditions, and to protect beneficial uses (FW-STD-WTR-02). Best management practices for livestock grazing management can be found in the Soil and Water Conservation Practices handbook (U.S. Department of Agriculture 1988a) and the National Best Management Practices for Water Quality Management on National Forest System Lands Technical Guide (U.S. Department of Agriculture 2012b). Controlling livestock distribution within a pasture or allotment, adjusting season of use to maintain and protect soil and water resources, and moving livestock when prescribed utilization levels are reached are a few examples of BMPs.

Overall, riparian management zone (RMZ) conditions in grazing allotments are expected to be maintained where they currently meet desired conditions and improve where they do not. When degraded conditions are documented at specific sites (for example, Clearwater bank stability), particularly those related to physical or biological features (PBFs) 1, 4, 5, 6 and 8, changes to annual operating instructions would be given to guide attainment of desired conditions. Steadily improving riparian conditions in grazing allotments would be expected to contribute to improvements in instream habitat to the benefit of the species addressed in this Final Environmental Impact Statement.

Recreation

Desired conditions include a minimal recreation footprint on aquatic habitat including the species and critical habitat addressed in this Final Environmental Impact Statement (FW-DC-ARREC-01). Two streamside dispersed recreation sites would be targeted for improvements or relocations every five years (FW-OBJ-ARREC-01). Newly developed recreation facilities would be kept out of floodplains or within 100 feet of water where feasible (FW-GDL-ARREC-01) to help protect riparian and instream conditions. Guidelines related to trail design, construction, and maintenance aim to prevent or minimize aquatic impacts (FW-GDL-ARREC-02-06).

Revised plan components aim to minimize and prevent background levels of riparian disturbance and streambank impacts caused by the recreation program. Over time, impacts to critical habitat from existing recreation sites would be mitigated, through project specific measures to reduce impacts or relocation or closure of the site altogether. Additionally, new recreation sites would not be approved if they caused adverse effects to water quality or aquatic resources (FW-GDL-ARREC-02). Localized effects to riparian vegetation, streambanks, woody debris, and water quality could still occur where heavy recreational use occurs and at some popular established recreation sites. FW-OBJ-ARREC-01 is aimed at reducing the impacts of these popular sites by mitigating, removing, or relocating two sites every five years, though impacts would still continue to occur until a project is proposed to address them. Adverse effects could therefore occur to physical and biological feature (PBF) 4 and PBF 8.

Lands and Special Uses

Effects under the revised plan would be expected to be the same as under the current plan. Effects to critical habitat from special uses would generally arise from occupation and use of riparian management zones (RMZs), and the general effects of soil compaction, stream bank disturbance, and effects to riparian vegetation (PBF 4). Existing special use permits were consulted on when salmon, steelhead, and bull trout were listed under the Endangered Species Act (ESA), or had site or permit-specific consultation, if appropriate. The primary revised standard for protecting federally listed aquatic resources, FW-STD-ARLND-01, states that: "When authorizing new lands special uses, or reauthorizing existing uses, include conditions to avoid or minimize adverse effects to fish, water, and riparian resources. If adverse effects are unavoidable to ESA listed fish, species of conservation concern, impaired water bodies, or stream habitat conditions, authorizations shall require actions that result in the re-establishment, restoration, mitigation, or improvement of conditions and ecological processes to ensure that projects that degrade conditions also include measures to improve conditions to the extent practicable. These processes include in-stream flow regimes, physical and biological connectivity, water quality, and integrity and complexity of riparian and aquatic habitat." A standard and guideline would also apply to new and existing hydropower facilities (FW-STD-ARLND-02, FW-GDL-ARLND-01). The potential and degree of risk to listed fish and critical habitat by lands and special uses are generally low and any specific actions would be subsequently reviewed on an individual basis with the revised standard (FW-STD-ARLND-01) as the basis for evaluation.

Watershed Restoration

The revised forest plan must incorporate watershed restoration direction from multiple sources which can give the appearance of conflicting restoration priorities. It can therefore be helpful to consider where and when each of the three primary sets of watershed restoration direction applies. The first set of watershed restoration direction are the water (WTR) plan components. These include twelve desired conditions and five objectives that are all forestwide (FW) components such that they would apply to all future management actions regardless of which watershed or what other type of status may also be applicable (priority watershed, conservation watershed network, etc.). These WTR plan components are grounded in the 2012 Planning Rule that requires "the plan must include plan components, including standards or guidelines, to maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area…" (U.S. Department of Agriculture 2012c).

The second set of watershed restoration direction is the requirement for forest plans to identify priority watersheds as part of the watershed condition framework (WCF). The WCF was designed in 2011 to establish a nationally consistent method for evaluating watersheds and provide a comprehensive approach for proactively implementing integrated restoration on priority watersheds on national forests and grasslands (U.S. Department of Agriculture 2011d); use of this national strategy in all forest plan revisions is also a requirement of the 2012 Planning Rule. A watershed restoration action plan (WRAP) must be completed for every watershed identified as a priority watershed under the WCF program that specifically identifies restoration actions needed to improve the overall watershed rating. The scope of the WCF program is broad and encompasses all Forest Service activities that contribute to improved watershed condition, including soil and water improvements, vegetation management, invasive species treatment, range management, wildlife and fisheries habitat restoration, road improvements, road decommissioning, and other activities. The intent is to utilize a holistic approach to treat whole subwatersheds from "ridge-top to ridge-top" to improve overall watershed condition.

The Nez Perce-Clearwater has completed three WRAPs to date (Fishing Creek, Upper Newsome Creek, and Meadow Creek) and is currently working on implementing WRAPs in three additional watersheds (Upper Elk Creek, Upper Clear Creek, and Upper Little Slate Creek). The Agricultural Improvement Act of 2018 authorized national forests to have up to five priority watersheds identified at any given time (U.S. Department of Agriculture 2018g). Under the revised plan, the national forest would evaluate and identify priority watersheds based on the need for restoration to improve overall watershed condition; alignment with other strategic objectives or priorities at the national, regional, or local level; alignment with priorities of other agencies and potential partners, and in consideration of available funding sources for potential WRAP actions. These watersheds would generally be the highest priority watersheds for focusing active restoration efforts as resources become available to meet the desired outcome of FW-OBJ-WTR-01: "Complete the actions identified in watershed restoration action plans for 15 priority watersheds as identified under the Watershed Condition Framework process every 15 years." Priority watersheds may or may not overlap geographically with the conservation watershed network (CWN).

The third set of watershed restoration direction is the CWN. PACFISH and INFISH originally called watersheds meant to focus on restoring native fish habitat "priority watersheds," but since that term was adopted by the watershed condition framework (WCF), the watersheds identified for emphasis on native fish are now called CWN watersheds in the revised plan to continue to meet the intent of PACFISH and INFISH direction (see Conservation Watershed Network section above and Appendix C for additional CWN details). At a minimum, restoration in CWN watersheds would become a priority when they happen to be in the action area of future integrated projects, but they could become an overall priority if CWN watersheds are also designated as a WCF priority watershed.

WCF Priority Watersheds can best be thought of as tactical and near-term designations guiding the implementation of agency work priorities in the near-term (that is, 5-year program of work), whereas Conservation Watersheds are more strategic and long-term designations helping to provide conditions that maintain or restore habitat for aquatic species in highly dynamic environments over the duration of a land management plan.

Under the revised plan, watershed restoration projects will promote the long-term ecological integrity of aquatic ecosystems (FW-DC-WTR-12, FW-GL-WTR-04). Priority watersheds identified in the revised plan include Upper Elk Creek, Upper Clear Creek, and Upper Little Snake Creek. Additions to the priority list would occur over the life of the plan and would require the development of WRAPs with the object to "complete the actions identified in watershed restoration action plans for 15 priority watersheds as identified under the Watershed Condition Framework process every 15 years" (FW-OBJ-WTR-01). Beyond this specific "priority" list, watersheds in the CWN would have high priority for restoration (FW-OBJ-CWN-01).

Short-term effects of implementing instream project elements are generally harmful to physical or biological features (PBFs) and listed species because plumes of suspended sediment can be created, and individual fish can be injured or killed during construction; dewatering project sites can also strand young-of-the-year fish. Fuel or hydraulic fluid leaks from heavy equipment can contaminate soil and streams. Equipment access points and work in riparian areas (for example, annual operating plan [AOP] installation) can locally disturb stream beds, banks, and surrounding vegetation.

However, long-term effects of implementing instream project elements are generally beneficial to PBFs and listed species because instream habitat and habitat forming processes are restored though these types of projects. Properly mitigated temporary negative effects are therefore dramatically outweighed by permanent long-term beneficial effects. For example, imposing new patterns of scour and deposition by installing instream habitat structures can redistribute existing spawning gravels. Installing instream wood can supplement local wood and gravel supplies, create or improve spawning and rearing habitat, and buy time for riparian treatments to have the desired effect of restoring natural channel forming processes. AOPs restore connectivity within watersheds, making more spawning and rearing habitat and temperature refugia available to listed fish as well as allowing hydrologic connectivity by conveying bed materials down the stream network (FW-DC-WTR-02). Much of this work would be accomplished through partnerships (FW-GL-WTR-02).

The revised plan aims to support functionally intact watersheds and critical habitat and thereby support native aquatic communities including listed fish (FW-DC-WTR-01/03/10). The plan includes specific targets of restoring 50 to 100 miles of unconfined stream channels (FW-OBJ-WTR-02) and 5 miles of confined channels (FW-OBJ-WTR-03) every five years. The riparian management zone (RMZ) definition (FW-STD-RMZ-01) and the associated objective FW-OBJ-RMZ-02 to improve riparian habitat aim to facilitate instream habitat improvement projects on the national forests. FW-STD-RMZ-01 was written in such a way as to specifically allow projects whose sole objective is to improve aquatic and riparian associated resources within the nearest 100 feet to the active stream channel. Outside the nearest 100 feet (an additional 200 feet in fish bearing streams), allow projects to benefit aquatic and riparian resources as well as to address fuel loading and silvicultural desired conditions provided it can be demonstrated (through multiscale analysis) that the project would not negatively impact the important functions of the outer area which include sediment filtering and large woody debris requirement. No commercial timber harvest may occur within the RMZ. While connectivity has been restored in many parts of the Nez Perce-Clearwater, new AOPs would aim to reconnect 10 to 20 miles of habitat every 5 years (FW-OBJ-WTR-04). Each of these restoration actions allowed and encouraged by the plan may have short term adverse effects to critical habitat followed by long term beneficial effects.

Proposed RMZ guidance would create opportunities for vegetation management to underplant native tree species in riparian areas, for example, that would move RMZs towards desired conditions of reference-like habitat in terms of their species diversity and structural complexity. Ecoregion-appropriate riparian stands would benefit instream habitats and the listed fishes that utilize them as the riparian, instream, and biological processes of interest evolved coincidently and are therefore dependent on each other.

Proposed projects completed under the new plan would undergo reviews via National Environmental Policy Act, Endangered Species Act, Magnussen-Stevens, and by the Army Corps of Engineers. Short-term and local adverse impacts to critical habitat would occur as restoration projects are implemented. PBF 8, which is sensitive to stream- bank or bed disturbance, could be adversely affected during project implementation but would be expected to quickly recover, within hours to days. Ultimately, all PBFs would benefit from restoration work.

Aquatic Plan Components

Under the action alternatives, all 1987 Forest Plan direction, the settlement agreement on the Clearwater Forest Plan lawsuit, PACFISH, INFISH, and provisions in the 1995 and 1998 Biological Opinions are replaced with the Nez Perce-Clearwater Aquatic Ecosystems plan components. The discussion below provides a comparison of the key attributes of the existing direction of the 1987 Forest Plans under the No Action Alternative to those in the Land Management Plan action alternatives.

The Land Management Plan focuses on managing toward desired conditions, or outcomes, rather than focusing simply on outputs. The following desired conditions are contained within the Aquatic Ecosystem plan components of the Land Management Plan:

FW-DC-WTR-01. National Forest System lands provide the distribution, diversity, and complexity of watershed and landscape-scale features including natural disturbance regimes and the aquatic and riparian ecosystems to which species, populations, and communities are uniquely adapted.

Watersheds and associated aquatic ecosystems retain their inherent resilience to respond and adjust to disturbances, including climate change, without long-term, adverse changes to their physical or biological integrity.

FW-DC-WTR-02. Spatial connectivity exists within or between watersheds. Lateral, longitudinal, and drainage network connections include floodplains, wetlands, upslope areas, headwater tributaries, and intact habitat refugia. These network connections provide chemically and physically unobstructed routes to areas critical for fulfilling life history requirements of aquatic, riparian-associated, and many upland species of plants and animals.

FW-DC-WTR-03. Aquatic habitats contribute to ecological conditions capable of supporting self-sustaining populations of native species and diverse plant, invertebrate, and vertebrate aquatic and riparian-dependent species. Aquatic habitats are key contributors for the recovery of threatened and endangered fish species and provide important habitat components for all native aquatic species.

FW-DC-WTR-04. Instream habitat conditions for managed watersheds move in concert with or towards reference conditions. Aquatic habitats are diverse, with channel characteristics and water quality reflective of the climate, geology, and natural vegetation of the area. Instream habitat conditions across the Nez Perce-Clearwater, such as large woody material, percent pools, residual pool depth, median particle size, and percent fines are within reference ranges as defined by agency monitoring (for example, PIBO) and match the frequency distribution of comparable reference sites for a given channel type, channel size, climate, and geomorphic setting.

FW-DC-WTR-05. Water quality, including groundwater, meets or exceeds applicable state water quality standards, fully supports designated beneficial uses, and is of sufficient quality to support surrounding communities, municipal water supplies, and natural resources. The Nez Perce-Clearwater has no documented lands or areas that are delivering water, sediment, nutrients, or chemical pollutants that would result in conditions that violate the State of Idaho’s water quality standards.

FW-DC-WTR-06. Sediment delivery to streams is of the types, quantities, and rates that support the natural instream sediment transport and storage rates and instream sediment substrate composition. The sediment regime in water bodies is not chronically affected by management activities to the extent that the availability of functioning spawning areas and interstitial spaces are reduced.

FW-DC-WTR-07. Instream flows are sufficient to create and sustain riparian, aquatic, and wetland habitats and to retain patterns of sediment, nutrient, and wood routing. The timing, magnitude, duration, and spatial distribution of peak, high, and low flows are retained. Stream flow regimes maintain riparian ecosystems and natural channel and floodplain dimensions. Stream channels transport sediment and woody material over time while maintaining reference dimensions (for example, bankfull width, depth, entrenchment ratio, slope, and sinuosity).

FW-DC-WTR-08. Groundwater dependent ecosystems, including peatlands, bogs, fens, wetlands, seeps, springs, riparian areas, groundwater-fed streams and lakes, and groundwater aquifers, persist in size and seasonal and annual timing and exhibit water table elevations within the natural range of variability. Surface and groundwater flows provide late-season stream flows, cold water temperatures, and sustain the function of surface and subsurface aquatic ecosystems.

FW-DC-WTR-09. Beavers are present in watersheds where their activities benefit ground water, surface water, and aquatic habitat complexity, and where their activities support conservation and recovery of imperiled aquatic species.

FW-DC-WTR-10. Critical habitat components (physical and biological features) provide the ecological conditions necessary to achieve species recovery. Spawning, rearing, and migratory habitats are widely available and inhabited. Listed aquatic species have access to historic habitat and appropriate life history strategies (for example, bull trout resident, fluvial, adfluvial; and anadromy for salmon and steelhead) are supported.

FW-DC-WTR-11. Water cooling mechanisms in unconfined channels that are dependent on the exchange of surface water and groundwater are functioning at full potential. Cooling mechanisms include dynamic scouring and bar formation, activation of side channels during high flow events, and inundation of the full floodplain extent during floods with an approximate 5- to 10-year return interval.

FW-DC-WTR-12. Watershed restoration projects promote the long-term ecological integrity of aquatic ecosystems and conserve the genetic integrity of native species.

FW-DC-RMZ-01. Riparian Management Zones reflect a natural composition of native flora and fauna and a distribution of physical, chemical, and biological conditions as compared to reference conditions. The species composition and structural diversity of native plant communities in riparian management zones provide adequate summer and winter thermal regulation, nutrient filtering, appropriate rates of surface erosion, bank erosion, and channel migration. Nutrients, large woody debris, and fine particulate organic matter are supplied in amounts and distributions sufficient to sustain physical complexity and stability.

FW-DC-RMZ-02. Riparian Management Zones feature key riparian processes and conditions that function consistent with local disturbance regimes, including slope stability and associated vegetative root strength, wood delivery to streams and within the riparian management zones, input of leaf and organic matter to aquatic and terrestrial systems, solar shading, microclimate, and water quality.

FW-DC-CWN-01. Conservation Watershed Networks have functionally intact ecosystems that provide high-quality water and contribute to and enhance the conservation of aquatic species of conservation concern and recovery of threatened or endangered fish species.

FW-DC-CWN-02. Streams within the Conservation Watershed Network provide habitat that supports robust native fish populations, which can expand to and recolonize adjacent unoccupied habitats. These areas conserve key demographic processes likely to influence the sustainability of aquatic species.

FW-DC-CWN-03. Roads in the Conservation Watershed Network present minimal risk to aquatic resources.

FW-DC-ARINF-01. The transportation system has minimal impacts on aquatic and riparian conditions through reduced hydrologic connectivity of roads to streams, lower sediment delivery to streams, reduced road impact to floodplains, and improved aquatic organism passage, where transportation infrastructure affects these features.

FW-DC-ARREC-01. Recreation facilities and their use, including trails and dispersed sites, have minimal impacts on aquatic resources, including threatened and endangered species, designated critical habitat, and aquatic species of conservation concern.

Riparian management zone widths included within FW-STD-RMZ-07 are mostly the same as PACFISH and INFISH. Exceptions include expanding the width of all Category 4 riparian management zones to 100 feet, where previously it was either 50 feet or 100 feet, and including intermittent streams that support fish at any time of the year as a Category 1 instead of a Category 4. These changes are more explicit in terms of what can or cannot happen within the zones, are based on best available science information and public input, and expand upon and clarify existing direction in PACFISH and INFISH.

Appendix A of the 1987 Nez Perce Forest Plan contained fish and water quality objectives, sediment yield and entry frequency guidelines, upward trend requirements for watersheds not meeting objectives that should occur concurrent with timber harvest, and a moratorium on sediment producing activities in Red River and Newsome Creek. Appendix K of the 1987 Clearwater Forest Plan included water quality objectives based on species present, as well as a litigation settlement agreement that allowed no measurable sediment increases with watershed improvement objectives. These historical directives were very effective at arresting habitat degradation during a time when management values were different, and land was being managed very aggressively (that is, extending the road network and harvesting close to streams on unstable ground). Management has since become more holistic, and in many cases, the old direction attempts to prevent effects that no longer occur with the use of modern best management practices.

The revised land management plan includes several plan components designed to address fish and water quality objectives, sediment yield, and trending toward desired conditions. FW-STD-CWN-01 and FW-STD-WTR-04 are intended to provide for improving stream conditions where they are currently degraded and suggest use of tools, such as multiscale analysis, to support the conclusion aquatic desired conditions will be met. Watersheds included in the Conservation Watershed Network (CWN) are expected to be those most important for long term conservation and recovery of threatened or endangered fish species and aquatic Species of Conservation Concern. FW-STD-CWN-01 applies everywhere in the CWN, including areas not currently under the Nez Perce Forest Plan. FW-STD-WTR-04 applies to all streams on the Nez Perce-Clearwater National Forest. Management approaches within Appendix 4 suggest the use of the Stream Condition Indicator Assessment to determine whether streams are meeting aquatic and riparian desired conditions. For both FW-STD-CWN-01 and FW-STD-WTR-04, where desired conditions are not being met, implementation of stream or riparian restoration actions will move indicators toward or maintain desired conditions. These actions will contribute toward Aquatic Ecosystem Objectives in meeting, enhancing, or restoring stream habitat.

Appendix A of the 1987 Nez Perce Forest Plan required the use of the sediment model for the Northern Region and Intermountain Region (R1/R4) to assess compliance with sediment yield guidelines. It was the intent of the previous Clearwater Forest Plan to use it as well. Specific sediment models are not required to be used in the Land Management Plan aquatic ecosystems plan components. The Nez Perce-Clearwater is moving away from being required to use a specific model. Many of the models that were required under the old forest plans (such as R1/R4) are now seen as outdated and suffered from a one-size-fits-all approach. These models were not applicable across the entire forest, and being tied to a specific model precluded the use of constantly evolving best scientific information and improvements in modeling technology. Rather, in assessing compliance with components, such as FW-STD-WTR-04, FW-STD-ARINF-07, FW-GDL-RMZ-02, and FW-GDL-ARINF-01, it is assumed that best available science will be used. Potential Management Approaches within Appendix 4 suggests the use of models, such as GRAIP-Lite, WEPP, and R1/R4, to collectively provide an assessment of existing condition and project effects and determine whether actions associated with projects would move conditions towards meeting desired conditions where not currently met or maintain desired conditions where currently met. These models allow for both short- and long-term estimates of sediment delivery, and the combination should be modeled. These components are intended to provide the same or enhanced direction as the 1987 Nez Perce Forest Plan Appendix A and the litigation settlement on the Clearwater National Forest.

FW-STD-WTR-04, in combination with other plan components, is intended to prevent long-term habitat degradation and not retard attainment of aquatic and riparian desired conditions. PACFISH and INFISH Biological Opinion (PIBO) data suggests static or improving habitat conditions when summarized at a broad scale (HUC8 or larger), since the late 1990s, after PACFISH and INFISH were implemented.

The Stream Condition Indicator Assessment and standards that refer to its use (FW-STD-WTR-04, FW-STD-RMZ-01, FW-STD-RMZ-06, FW-STD-CWN-01) in conjunction with PIBO monitoring, offer the same or an enhanced yardstick as Riparian Management Objectives (RMOs) from PACFISH, to assess effectiveness of the components in achieving aquatic desired conditions. FW-DC-WTR-04 replaces a set of fixed habitat metrics as a desired condition (RMOs in PACFISH). This plan component describes desired stream conditions in terms of a range of conditions established from data from reference conditions, with the understanding that, even in reference streams, habitat is dynamic and changes in response to natural disturbances. The desired condition for streams states the range of conditions in managed streams moves in concert with conditions within the range of reference.

FW-DC-WTR-04 is a higher bar than the 1987 Nez Perce Forest Plan Appendix A fish or water quality objectives in the No Action Alternative, where fish or water quality objectives range from 100 percent in “pristine” watersheds to 70 percent. The 1987 Nez Perce Forest Plan also allows a measure of degradation in some watersheds, describing the existing condition as 100 percent but assigning a fish or water quality objective of 70 percent. The Aquatic Ecosystems plan components specify desired condition as functioning at 100 percent.

The Stream Condition Indicator Assessment included in Appendix 4, Potential Management Approaches, which describes desired condition and natural range for each stream and riparian function. The assessment determines whether stream and riparian processes are functioning at desired conditions. For those processes functioning at low or medium level, stream or riparian restoration actions should be implemented to move those processes toward desired conditions. For plan components FW-STD-CWN-01, FW-STD-RMZ-01 (timber harvest within RMZ), and FW-STD-RMZ-6 (prescribed fire in RMZ), multiscale analysis, in addition to completing the Stream Condition Indicator Assessment, shows where indicators are not functioning at high level.

Multiscale analysis replaces watershed analysis that was used in the 1987 Forest Plans. Watershed analyses were completed for projects that proposed harvest within the riparian habitat conservation area. Under the revised Land Management Plan, to show compliance with FW-STD-CWN-01, FW-STD-RMZ-01, and FW-STD-RMZ-06, multiscale analysis, as described in Appendix 4, Potential Management Approaches, determines consistency with these standards. Stream and riparian conditions not meeting desired conditions would include aquatic restoration to maintain or move toward desired conditions, including the use of wildland fire to move toward those desired conditions.

Conservation Watershed Network

Conservation Watershed Networks (CWNs) are an outgrowth of a suite of policy guidance including PACFISH, INFISH, and Interior Columbia Basin Ecosystem Management Project (ICBEMP). PACFISH and INFISH were intended provide temporary guidance and were expected to be replaced by ICBEMP in 2000. Because the incoming administration did not make a decision in 2000, further scientific guidance from ICBEMP was received in 2003 and amended in 2014 that provided guidance specific to the Columbia River basin. The concept of CWNs builds upon what has been learned from PACFISH, INFISH, and ICBEMP, including Key Watershed guidance found in PACFISH (U.S. Department of Agriculture and U.S. Department of the Interior 1995a) and priority watershed guidance found in INFISH (U.S. Department of Agriculture 1995d). Under both sets of guidance, key and priority watersheds were selected to protect population strongholds. Selected watersheds were expected to provide a pattern of protection across the landscape where the habitat of threatened and endangered fish and Species of Conservation Concern (SCC) received special attention and treatment. For the Aquatic Ecosystems plan components, major and minor spawning areas identified in the Snake River Recovery plans for steelhead and spring and summer Chinook, presence of a bull trout local population identified in the Columbia River bull trout recovery plan, designated critical habitat for one or more endangered fish species, spawning and rearing habitat for Pacific lamprey, and reaches where models predict to have occurrence of bull trout in 2040 (Isaak et al. 2015) were the criteria used to include watersheds in the CWN.

The CWN is a well distributed and connected set of watersheds that provide the principal production areas for maintaining and restoring the populations, including providing resiliency during and after disturbance events and as the effects of climate change occur. The CWN plan components emphasize maintenance or restoration of spawning, rearing, and migration habitat that supports Endangered Species Act (ESA) listed and SCC fish populations.

For those efforts to be effective for listed species within the network of watersheds represented by the CWN, it is vital that project planners are aware of and consider the types of aquatic restoration that help alleviate factors most limiting the production of ESA listed and SCC juvenile outmigrants from the Nez Perce-Clearwater watersheds.

Conservation Watershed Networks are the highest priority for restoration actions for the aquatic environment. Conservation Watershed Network components contain an emphasis on watershed restoration, in addition to standards and guidelines. Desired conditions within the CWN focus on functionally intact ecosystems that contribute to and enhance conservation of aquatic species of conservation concern, recovery of threatened or endangered fish species, providing habitat capable of supporting robust fish populations that can expand and recolonize adjacent unoccupied habitats, and forest roads that present minimal risk to aquatic resources. Objectives emphasize assessing roads (FW-OBJ-CWN-01) that negatively interact with streams and storm proofing roads prioritized for restoration (FW-OBJ-CWN-02). Restoration would be achieved through the collective objectives within Aquatic Ecosystem plan components. Aquatic restoration is also encouraged in HUC 12 sub-watersheds outside of the CWN that are important for meeting recovery of listed species.

Conservation Watershed Networks in the Land Management Plan replace Key and Priority Watersheds under PACFISH and INFISH. According to plan component FW-STD-CWN-01, use Stream Condition Indicator Assessment and multiscale analysis for all HUC12 watersheds that are considered CWN. The completion of the assessment and multiscale analysis guides stream and riparian restoration actions that contribute towards the recovery of federally listed species and the achievement of these desired conditions and does not retard them. Under FW-STD-ARINF-07, when projects are constructing or reconstructing roads within CWN or HUC12 sub-watersheds with critical habitat or listed aquatic species, projects shall result in a net decrease in the hydrologic connectivity of the road system and stream channel network. FW-STD-ARLND-03 and 04 provide protection for sub-watersheds when hydroelectric and water developments are to be authorized or developed.

The Biological Opinion entitled "Land and Resource Management Plans for National Forests and Bureau of Land Management Resource Areas in the Upper Columbia River Basin and Snake River Basin Evolutionarily Significant Units" (NMFS 1998) included special management considerations for the Selway River incorporated into the action to avoid a jeopardy determination for Snake River steelhead. These protections afforded in that biological opinion will be superseded by the biological opinion on the revised forest plan. However, in the revised forest plan, there will still be special consideration for much of the Selway, for example, 22 sub-watersheds are included in the CWN in the Selway basin, including these HUC12 sub-watersheds: Upper Running Creek, Lower Running Creek, Upper Bear Creek, Paradise Creek Middle Bear Creek Lower Cub Creek, Lower Bear Creek, Elk Creek-Selway River, Upper East Fork Moose Creek, Middle East Fork Moose Creek, Middle North Fork Moose Creek, Rhonda Creek, Lower North Fork Moose Creek Lower East Fork Moose Creek, Moose Creek, Marten Creek, Headwaters Meadow Creek, Upper Meadow Creek, Middle Meadow Creek, Buck Lake Creek, Lower Meadow Creek, and O'Hara Creek.

Based on the information presented above, it is expected that implementation of the action alternatives would result in the same or similar outcomes as the No Action Alternative for the following reasons:

1. direction in the Aquatic Ecosystems plan components is designed to build and strengthen on that in PACFISH and INFISH.
2. these plan components are designed to carry forward the principle of improved aquatic habitat from the 1987 plans as amended by PACFISH and INFISH.
3. the plan components are designed to provide clarification for direction that is ambiguous in the No Action Alternative.

It is possible that improving trends that are evident in some subbasins will be initiated in others where there is presently no improvement indicated, such as the Lower Clearwater. In any case, degradation of existing conditions is not expected and improving trends are expected to be supported and not retarded by the action alternatives.

Aquatic Ecosystem objectives emphasize restoration in priority watersheds identified under the CWN. Other objectives apply to all watersheds across the Nez Perce-Clearwater and focus on restoration within unconfined and confined channels, reconnecting habitats and improving soil and watershed conditions. Under FW-OBJ-WTR-02, restoration of stream habitat within unconfined channels would occur to maintain or restore connectivity, structure, composition, and function of habitat for fisheries and other aquatic species in streams with legacy effects that caused channels to become straightened or incised, impaired beaver habitat, or diminished floodplain capacity. Types of activities that would be likely to contribute to this objective include berm removal, large woody debris placement, streamside road decommissioning, riparian planting, beaver dam analogs, and process-based restoration or floodplain restoration. For FW-OBJ-WTR-03, restoration within confined channels would improve step pool structure, composition, and function of habitat for aquatic species. Types of activities that would be likely to contribute to this objective include improving stream complexity, large wood debris or boulder placement, and riparian planting. FW-OBJ-RMZ-01 would improve riparian habitat through improvements that are intended to meet desired conditions for riparian management zones (RMZs), such as road obliteration, riparian planting, hardwood restoration, post assisted log structures, beaver dam analogs, and reconnecting floodplains by removing road prisms or berms. Under FW-OBJ-02, when harvest occurs within the RMZ, a minimum of 10 percent of trees beyond 150 feet (RMZ Category 1) and beyond 100 feet (RMZ Categories 2 and 3) from the edge of the active stream channel would be used for aquatic stream restoration either on-site or offsite to contribute large wood to stream channels.

The rate of watershed and aquatic restoration would increase under all the action alternatives when compared to the No Action Alternative. The following objectives include aquatic restoration activities that are set to occur every five years.

FW-OBJ-WTR-01. Complete the actions identified in watershed restoration action plans for 15 priority watersheds as identified under the Watershed Condition Framework process every 15 years.

FW-OBJ-WTR-02. Enhance or restore 50 to 100 miles of stream habitat within naturally unconfined channels every 5 years to maintain or restore connectivity, structure, composition, and function of habitat for fisheries and other aquatic species in streams with legacy effects that caused channels to become straightened or incised, impaired beaver habitat, or diminished floodplain capacity. Activities include, but are not limited to, berm removal, large woody debris placement, streamside road decommissioning, riparian planting, beaver dam analogs, and process-based restoration/floodplain restoration.

FW-OBJ-WTR-03. Enhance or restore stream habitat on 5 miles, every 5 years, in naturally confined channels to maintain or restore step pool structure, composition, and function of habitat for fisheries and other aquatic species. Activities include, but are not limited to, improving stream complexity, large wood debris or boulder placement, and riparian planting.

FW-OBJ-WTR-04. Reconnect 10 to 20 miles of habitat in streams every 5 years where passage barriers created by roads or culverts are limiting the distribution of fish or other aquatic species of concern.

FW-OBJ-WTR-05. Improve soil and watershed conditions on 3,000 to 4,000 acres every 5 years, emphasizing actions in priority watersheds and Conservation Watershed Network watersheds. This includes non-system road decommissioning.

FW-OBJ-CWN-01. Conservation Watershed Networks are the highest priority for restoration actions for native fish and other aquatic species. Assess 500 miles of maintenance level 1 (for example, intermittent stored) roads every 5 years to identify those roads that may negatively impact streams, such as contributing excessive sediment or altering riparian areas or floodplains.

FW-OBJ-CWN-02. Stormproof roads in Conservation Watershed Network prioritized for restoration every 5 years as funding allows to benefit threatened and endangered aquatic species and municipal watersheds. Emphasize roads with greatest risk of erosion and road prism failure, including maintenance level 1 & 2 roads.

FW-OBJ-CWN-02P. Stormproof 15 percent of roads in Conservation Watershed Network prioritized for restoration.

FW-OBJ-RMZ-01. Improve 300 to 700 acres of riparian habitat every 5 years, through improvements that are intended to meet desired conditions for riparian management zones, such as road obliteration, riparian planting, hardwood restoration, post assisted log structures, beaver dam analogs, and reconnecting floodplains by removing road prisms or berms.

FW-OBJ-RMZ-02. On an annual basis, a minimum of 10 percent of trees harvested in the portions of the Riparian Management Zone beyond 150 feet (Riparian Management Zone Category 1) and beyond 100 feet (Riparian Management Zone Categories 2 and 3) from the edge of the active stream channel are used for aquatic stream restoration either on-site or off-site to contribute large wood to stream channels.

FW-OBJ-ARREC-01. Mitigate, remove, or relocate two existing dispersed recreation sites from within riparian management zones to outside of riparian management zones every 5 years.

Management within the Riparian Management Zones

FW-STD-RMZ-01 (standard TM-1 in PACFISH) is intended to provide clarification of direction in the No Action Alternative related to silvicultural treatments in riparian management zones (RMZs) by describing the conditions under which these activities, including timber harvest, might be appropriate in RMZs. It is expected that some level of harvest in RMZs would occur under the action alternatives, which would exceed levels harvested since 1995 under direction in the No Action Alternative. Harvest in RMZs conducted according to the constraints outlined in FW-STD-RMZ-01 is not expected to result in additional effects for the following reasons:

The main premise in this standard is the same as TM-1 in PACFISH because it sets the expectation that timber harvest will be conducted in RMZs where needed to achieve aquatic desired conditions. The language further clarifies the direction found in TM-1 regarding conditions under which timber harvest is permitted in riparian areas by adding the word "only" [emphasis added] in FW-STD-RMZ-01 as shown in the following quote:

"Vegetation management shall ***only*** occur in riparian management zones from the edges of the active stream channel to … (*various distances depending on the RMZ category*)… to restore or enhance aquatic and riparian-associated resources".

Contemporary science supports the conclusion that this level of activity in riparian management zones is sufficient to maintain stream conditions. Initial studies completed by Chen et al. (1993) and the Forest Ecosystem Management Assessment Team (1993) suggested that streamside buffers of over 400 feet were needed to protect ecological processes such as wind speed and humidity near streams, which at the time were thought to potentially increase stream temperature. This finding was partially responsible for the second tree height, which added another 150 feet on each side of the creek to riparian habitat conservation areas, applied to riparian reserve and riparian habitat conservation area widths in PACFISH and INFISH (Everest and Reeves 2007, Reeves, Pickard, and Johnson 2016). More recently, many researchers have suggested that a 100 foot buffer next to fish-bearing and perennial streams is generally likely to be sufficient to protect against stream temperature increase (Anderson and Poage 2014, Reeves, Pickard, and Johnson 2016, Sweeney and Newbold 2014, Witt et al. 2016). Even so, consideration of context and geography is also appropriate. In a discussion of fixed-width riparian buffers, Richardson et al. (2012) stated that although these types of protections are administratively simple to implement at a reach scale, watershed considerations and location within the catchment provide additional important context. Reeves et al. (2016) stated that, with the tools currently available, widths can be more easily adjusted and justified for both wider and narrower buffers.

Regarding the riparian width needed to ensure streamside wood delivery to streams, debate and scientific inquiry have continued since PACFISH and INFISH were adopted. Studies have been completed to help identify where wood in streams comes from (Reeves et al. 2003, Benda and Miller 2003) and the fate of wood once it is delivered above or to the stream (Beechie et al. 2000). In addition to streamside delivery, disturbance combined with topography can deliver a significant percentage from outside riparian management zones, especially steeper watersheds that are more dissected. Models have also been developed to help identify the likelihood of riparian trees being delivered to the stream channel (Benda et al. 2003, Meleason et al. 2003, Pollock et al. 2012, Spies et al. 2013, Welty et al. 2002). Models focused on wood delivery from the riparian areas consider distance from the stream, median tree height, and the direction that trees fall. Modeling completed by Meleason et al. (2003) found that greater than 90 percent of wood was contributed from within 100 feet of the stream edge for modeled conifer riparian stands in western Oregon and Washington. In a literature review, Spies et al. (2013) found that 95 percent of wood delivered to streams from hardwood stands came from within 82 feet, and from conifer stands from within 148 feet, in forests in the western cascades of Oregon and Washington.

Third, additional components intended to address potential effects from harvest activities in riparian management zones (RMZs), particularly increases in sediment delivery from soil disturbance, are included. Guidelines FW-GDL-RMZ-01, 02, and 03 would restrict timber harvest activities that could result in ground disturbance that might lead to sediment input to streams or wetlands. FW-STD-ARINF-03 and FW-GDL-ARINF-01 address sediment from road construction and reconstruction, including temporary roads.

And fourth, use of the Stream Condition Indicator Assessment and completion of a multiscale analysis are management approaches that can be used to demonstrate the ecological need for the proposed activity and to document that it maintains or improves existing stream habitat and avoids adverse effects to threatened and endangered species and their designated critical habitat. A favorable assessment of the compilation of information obtained from using these tools would support the conclusion that FW-STD-RMZ-01 is met. FW-STD-WTR-04 also provides direction that activities shall maintain existing aquatic conditions where Aquatic Ecosystems plan components desired conditions are met and restore or not retard their attainment where not met. The Stream Condition Indicator Assessment or a similar tool, can be used in conjunction with, or as a part of, multiscale analysis or other equivalent analysis tools to determine if these standards are being met when harvest is proposed in riparian management zones.

Aquatic Species Environmental Consequences

Effects of Forestwide Management on Aquatic Species

Watersheds throughout the Nez Perce-Clearwater support populations of five listed fish species, one species of conservation concern, and five regional forester aquatic sensitive species. Several areas are protected through congressionally designated wilderness areas, inventoried roadless, and eligible wild and scenic rivers. These areas have significant overlap with Conservation Watershed Network sub-watersheds.

No Action Alternative

Past management has resulted in degraded conditions across many watersheds within the Nez Perce-Clearwater. Habitat for aquatic species is impaired from the effects of human influence over the past 150 years. Watershed restoration efforts to restore aquatic, riparian, and terrestrial habitat have been underway since the 1980s. Continuing with the existing management and current levels of aquatic restoration would produce a slow improving trend for some watersheds, while others would remain in their current condition. Under the existing forest plans, both national forests have consistently implemented restoration work, along with partners, to meet forest plan fish and water quality objectives. Restoration actions have primarily focused on road decommissioning and roaded stream crossing upgrades to pass 100-year flows and allow for aquatic organism passage. Other activities have focused on riparian and meadow restoration and have included rehabilitating abandoned mines, planting native vegetation, stabilizing stream banks, fencing riparian and wetland areas, removing streamside mine tailings, improving stream habitat, and large woody debris placement. These activities have resulted in decreased sediment delivery and have improved riparian function and stream processes. These activities would continue under the No Action Alternative if the Nez Perce-Clearwater continues to prioritize watershed restoration and emphasize partnership opportunities, especially with the Nez Perce Tribe. Stewardship funding and retained receipts are current budget sources used for restoration projects and would likely continue under the No Action Alternative.

There would continue to be localized improvements to watershed, soil, riparian, and aquatic habitat conditions as projects are implemented, but watershed-scale improvements may occur slowly given current and anticipated funding levels. With the direction and emphasis in the Land Management Plan, watershed restoration may tend to be prioritized and directed by more commodity-based resource decisions, such as restoration associated with timber harvest activities and integrated vegetation restoration projects.

Effects common to all action alternatives

Endangered Species Act Listed Fishes

There are several factors to consider in assessment of how forest management is expected to affect Endangered Species Act listed salmonids at a population level including salmonid life history, the magnitude of various current threats, outcomes of aquatic restoration, advancements in forestry practices, as well as current conditions and protections on the Nez Perce-Clearwater. Although forest management in the past has been a threat to aquatic species, progress in environmentally responsible forest practices provides tools to mitigate for many of the previously detrimental effects of management. In addition, many of the most salient current threats to anadromous salmonids in the Columbia and Snake rivers occur off of the national forest and are not related to national forest management, which limits the national forest's potential to mitigate for these threats. It is important to note that the Forest Service is not solely responsible for recovery of endangered species, but as part of its stewardship, is responsible for providing ecological conditions required under § 219.9 to contribute to the recovery of federally listed threatened and endangered species, conserve proposed and candidate species, and maintain a viable population of each species of conservation concern. The responsibility for administering recovery of endangered species lies with the U.S. Fish and Wildlife Service and National Oceanic and Atmospheric Administration Fisheries.

There have been recent ecological (Welch et al. 2020)and economic (Jeager and Scheurell, 2023) analyses that question the contribution of freshwater aquatic restoration to basin-wide Endangered Species Act listed salmon recovery. The observed lack of a strong response at the basin level that these authors reported is not surprising given the life history of these fish, considering the physical location and salmon life stage where many current threats occur. Pacific salmon exhibit a type-3 survivorship curve (Demetrius 1978), with high fecundity and most mortality occurring early in life. Although a great deal of research concerning threats to salmonid recovery has focused on smolt mortality during the early freshwater rearing and migration period, because of the inherent life history, it is difficult to show that any early mortality is not compensatory, and mortality that is not additive is not capable of strong population level effects. For example, see the discussion of avian predation in Haeseker et al. (2020) and Payton et al. (2020), who arrived at different conclusions from similar data. Conversely, adult mortality in an organism with a type-3 survivorship curve is paramount and exerts a much stronger population level influence. Accounting for smolt-to-adult return rates, juvenile mortality often has to be several thousand times greater to equal adult mortality's effect on a population. Some recent studies have attempted to incorporate this principle by interpreting smolt mortality via the concept of adult equivalence (Tiffan et al. 2020, Chasco et al 2017b), but more research is needed to provide a comparative accounting of mortality threats to Pacific salmon over their life cycle.

There are many factors affecting anadromous salmonid recovery that have been reported. These continue to be analyzed and debated in the literature, including but not limited to, effects of hydropower facilities (Budy et al. 2002, Schaller and Petrosky 2007, Muir et al. 2006, Keefer et al. 2004, Rechisky et al. 2009, 2013, 2014, Welch et al. 2008, Hilborn 2013); atmospheric circulation, primarily the Pacific Decadal Oscillation (PDO), North Pacific Gyre Oscillation (NPGO), El Nino Southern Oscillation (ELSO) effects on ocean conditions (Johnstone and Mantua 2014, McFadden and Zhang 2002, Schollaert Uz et al, 2017, Kilduff et al. 2015 Gosselin et al 2021); avian predation during both estuary migration (Schreck et al. 2006, Ryan, et al. 2003, Evans et al. 2019) and ocean residence (Philips et al 2021); increased ocean mortality from sharks and orcas (Manashin et al 2021, Adams et al 2016, Seitz et al. 2019, Ohlberger et al 2019); competition from pink salmon (Ruggerone and Nielson 2004, Batten et al. 2018); sport and commercial fisheries (Lindsay et al. 2004); commercial bycatch (Ricker 1976, Wertheimer 1988); and pinniped predation on late-stage juveniles and adults in the estuary and ocean (Chasco et al. 2017a, Chasco et al. 2017b, Wright et al. 2007, WSAS 2022) that likely have greater population-level effects than forest management, simply because they occur at later life stages, when mortality is more likely to be additive.

Because there are so many threats, the varying effect of mortality by age, and the prevalence of strong population level effects outside the window of forest stream habitation, it is not surprising that regional assessments would fail to find direct relationships between funding and freshwater activity levels on population recovery. By design, habitat restoration projects achieve progress at incremental scales, generally one stream reach at a time. These incremental improvements in habitat may not have large enough effects to compensate for larger factors that occur throughout a species' range until they reach a critical threshold (Roni et al. 2010). However over time, as aquatic habitat improvements accumulate in an area of interest, they can provide beneficial effects at local scales, especially in terms of resilience of local populations. For example, large-scale stream restoration in the Lemhi basin did result in local benefits that were hypothesized to increase population resilience but did not result in population increases (Copeland et al. 2020). For fish and aquatic organisms that are likely to face climate change effects over the life of the plan, it is increasingly important to prioritize mitigation and restoration actions on those that are likely to increase population resilience (Beechie et al. 2023). Increasing population resilience is especially important for populations that appear to exhibit density dependence in freshwater like spring Chinook and steelhead (Walters et al. 2013), highlighting the importance of expanding and maintaining connectivity and expanding suitable habitat through restoration.

Regardless of the outcome of the continuing academic discussions concerning the intensity of various threats to salmon recovery, or the merits of aquatic restoration to Endangered Species Act (ESA) recovery of Columbia basin salmonids, the Nez Perce-Clearwater National Forest is bound by law and policy to conduct management activities in ways that mitigate for effects of forest management to ESA listed species. Meeting these requirements occurs for each individual project through ESA consultation and National Environmental Policy Act (NEPA) analysis where appropriate. The 2012 Planning Rule requires that the national forest contribute to ESA recovery at section 219.9. The definitions in the planning rule define recovery as "The improvement in the status of a listed species to the point at which listing as federally endangered or threatened is no longer appropriate." The directives further explain that development of, or changes to, plan components to provide for ecological conditions for threatened and endangered species should be based on a need to change the plan identified from the assessment of the ecological conditions necessary to contribute to their recovery and maintaining or restoring critical habitats (FSH 1909.12, ch. 10, sec. 12.55), or from information brought forward during the public and governmental participation process. (1909.12_20.23.13a). It is important to acknowledge that although the national forest supports recovery by considering recovery plans and integrating them into plan content and analysis, it is beyond the authority and responsibility of the Forest Service to solely achieve recovery for a species like salmon that spend so much of their life outside of National Forest System lands. Additionally, the administrative authority for ESA recovery lies with the U.S. Fish and Wildlife Service and the National Marine Fisheries Service and is implemented through the development of recovery plans. The following text from National Oceanic and Atmospheric Administration describes the process and role of recovery plans:

"The Endangered Species Act requires National Marine Fisheries Service to develop recovery plans for listed salmon and steelhead species. The U.S. Fish and Wildlife Service develops and implements recovery plans for bull trout. Recovery Plans focus on collaborative planning that draws on collective knowledge, expertise, and partnerships. Recovery plans include the following elements: measurable goals for delisting the species from the Endangered Species Act, factors limiting viability, actions to address limiting factors, and recovery estimates.
The Endangered Species Act requires periodic reviews of species that are listed as threatened or endangered to ensure that the listing is still accurate. The review will determine whether species should be removed from the list or be changed in status from an endangered species to a threatened species or from a threatened species to an endangered species. These reviews are known as '5-year reviews.'
A 5-year review may result in a recommendation to reclassify or delist a particular species. The criteria for reclassification or delisting are based on reducing the five listing threat factors described in the species' final listing rule and recovery plan. A species' listing status can only be changed by the rulemaking process. Species may be removed from the endangered or threatened species list for three reasons: 1) The species has recovered to such an extent that it no longer needs Endangered Species Act protection. 2) The original information warranting listing has been shown to be incorrect, or new information suggests that the species is not actually endangered or threatened. 3) The species has become extinct. A 5-year review may also result in a recommendation to maintain the species' current classification status of threatened or endangered."
(https://www.fisheries.noaa,gov/national/endangered-species-conservation/endangered-species-act-5-year-reviews)

The 5-year status reviews and recovery plans provide a basic framework on how present watershed conditions limit the fish production by individual population or area of the listed species. Information from recovery plans, five-year status reviews, and research on the effectiveness of habitat restoration for fish production will evolve over the duration of the Land Management Plan. This information is valuable to project planners, especially through coordination with watershed partners from tribes; local watershed groups; and county, state, and federal agencies, including the U.S. Fish and Wildlife Service (USFWS) and the National Marine Fisheries Service.

The Nez Perce-Clearwater National Forest strives to fulfil its obligations to supporting recovery by considering and incorporating elements of the recovery plans into land management plan content. For aquatic species, this was primarily achieved through forest plan Section 7 consultation with the USFWS and National Marine Fisheries Service, as well as in cooperative sessions through the

Aquatic and Riparian Conservation Strategy (ARCS) working group, where cooperating agency and partner resource specialists had the opportunity to collaborate in reviewing the best available scientific information and provide input on language and determine the final form of plan components.

The Endangered Species Act (ESA) recovery plan continues to list freshwater threats that occur on National Forest System lands as limiting to recovery, including degraded habitat that persist across the basin, with simplified stream channels, disconnected floodplains, impaired instream flow, loss of cold water refugia. Many activities allowed by the revised plan within the Nez Perce-Clearwater National Forest have the potential to indirectly affect individual ESA listed fish and critical habitats in a beneficial or negative manner. Land management activities that disturb the soil surface or require added use of already disturbed features such as road prisms have a greater potential to interact and potentially cause adverse effects. Salmonids that overwinter (such as spring Chinook and steelhead) or otherwise have longer residence times in freshwater (such as bull trout) have greater potential to be affected than species with shorter freshwater residence (like fall Chinook) or migration times (like sockeye). Activities that have the greatest potential to disturb soils and indirectly affect ESA listed fish and critical habitat include some activities associated with vegetation management, fuels management, livestock grazing, roads, and recreation. While the cause-and-effect relationships from land management activities are not linear and are often indirect, results from PACFISH and INFISH Biological Opinion (PIBO) monitoring over the past 19 years has shown that with PIBO standards and guidelines applied consistently across the interior Columbia Basin, habitat degradation has been arrested and habitat conditions on nearly all National Forests are trending in a positive direction (Roper et al. 2019, Thomas et al. 2018).

With PACFISH and INFISH components updated and mostly carried forward in the proposed action, ESA listed fish habitat in the planning area is expected to continue a similar improving trend if similar standards and guidelines continue to be applied as they have in the last two decades. While larger vegetation restoration projects involving extensive road reconditioning and haul are likely to contribute fine sediment to streams at crossings and in locations where the road is close to and paralleling the stream, the active delivery is relatively short term, and in most instances, a relatively small amount is delivered when compared against management that occurred prior to PACFISH and INFISH. With culvert replacement and best management practice (BMP) use occurring before and during project work, and road storage applied when projects conclude, roads likely contribute less sediment than they otherwise would have before use. Of equal and likely greater importance, the sediment caused by current road use and harvest methods cannot be compared to the types of roads being built, the amount being built, and their locations prior to PACFISH and INFISH. The plan components in the revised plan are expected to continue the passive restoration occurring across much of the Interior Columbia Basin (Roper et al., 2019). Also, the identification of a Conservation Watershed Network (CWN) and objectives to reduce the interactions between roads and streams meet much of the intent of the unsigned Interior Columbia Basin Ecosystem Management Project (ICEBMP) that was expected to refine INFISH (U.S. Department of Agriculture, Forest Service, 1995b). Active restoration in key locations based on watershed condition framework (WCF) and the CWN are expected to further contribute to improving habitat conditions in managed portions of watersheds on federal lands.

Although the primary driver of changes in anadromous fish (such as spring and summer Chinook) abundance in Idaho is usually attributed to marine conditions (NOAA, 2022), freshwater habitat quantity and quality can amplify or attenuate changes in abundance, especially if there are population bottlenecks identified in freshwater habitat (Wilson et al. 2021). While detrimental effects of historical forestland management practices to fish habitat have been widely reported in the literature (Espinosa et al. 1997) Gibbons and Salo 1973, Ringler and Hall 1975, Culp and Davies 1983, Doeg and Koehn 1990), the effectiveness of modern practices at preventing degradation has also been widely reported, highlighting the effectiveness of tools like BMPs, and leaving riparian buffer strips (Newbold et al. 1980, Murphy et al. 1986, Warrington et al. 2017). In addition, some researchers have reported positive effects of forest management on juvenile salmonid production growth, or survival (Bilby and Bisson 1987, Gregory et al. 1988, Thedinga et al. 1989, Hicks et al. 1991).

A recent broad-scale study from British Columbia (Peacock et al. 2023) investigated relationships between 10 freshwater habitat pressure indicators (percent of agricultural development, percent urban development, percent riparian disturbance, percent linear development, kilometers of forestry roads, kilometers of non-forest roads, stream crossings per kilometer, percent forest disturbance, equivalent clearcut area, percent mountain pine beetle defoliation) that were hypothesized to have strong effects on salmon spawner abundance. The authors reported that evidence of relationships was weak across the entire province, and “variable in direction and magnitude at the watershed scale.” However, their vulnerability assessment was successful at identifying at-risk populations at smaller scales, and the authors reiterated the benefit of using multi-scale analysis to identify local population vulnerabilities (Peacock et al. 2023). As the authors observed, the lack of a strong province-wide relationships does not necessarily mean there are no effects (Peacock et al. 2023), but rather illustrates that effects of forestry management can differ greatly by locality, highlighting the need for site specific analysis using tools such as multi-scale analysis, which under the revised forest plan, will be available at the project level. It is also possible that the lack of expected strong negative effects reported in Peacock et al. (2023) is in part attributable to the province-wide adoption of the Forest and Range Practices Act in 2002, which required that BMPs be applied to forest management in British Columbia. Paired-watershed studies conducted over a nine-year (2006 to 2014) period in Oregon (Bateman et al. 2018, 2021) examining the effects of modern timber harvest (using BMPs) on trout and salmon failed to document any negative effects on fish from clearcutting, and in fact reported temporary positive effects on trout growth and abundance in harvest units post-logging, primarily due to increased stream productivity caused by the increase in light and temperature from the increase in forest canopy openings.

In addition, there are indications that freshwater habitat quality in much of Idaho is not functioning as the major population bottleneck for anadromous salmonids in north-central Idaho (NOAA 2017). For example, Thurow et al. (Thurow et al. 2020)), in an analysis on the production potential of the middle fork Salmon River (adjacent to the national forest), observed that:

“Although conditions are degraded in small, localized areas outside wilderness, habitats throughout most of the (Middle Fork Salmon River) are in excellent condition (NMFS 2017). Historical grazing, mining, and road impacts are being mitigated by natal habitat restoration efforts outside wilderness boundaries…(in various specific locations).”

Although this statement was specifically referring to an adjacent forest, this scenario is mirrored on the Nez Perce-Clearwater National Forest, where large tracts of intact high-quality habitat remain protected by protective land allocations and wilderness designation, and passive and active restoration are working toward improvement of degraded habitat in areas outside wilderness and roadless boundaries. In a modeling exercise that estimated carrying capacity and 24-year extinction risk of the Snake River evolutionary significant unit (ESU) of spring Chinook salmon, Hinrichsen and Paulsen (2020) reported low extinction probabilities for the two populations they analyzed on the Nez Perce-Clearwater, which happen to be largely protected by land allocations.

In addition to protecting Endangered Species Act listed fishes, the plan components are expected to move the landscape toward desired conditions based on natural range variation (NRV) by introducing disturbance back onto the landscape. The importance of attaining these ecological conditions to fisheries and aquatic ecosystems cannot be overstated. With the range of climate threats that are expected in the future, the best chance for recovery and persistence lies in attainment of desired conditions that are based on NRV. The NRV on the Nez Perce-Clearwater included frequent natural disturbance including fire, landslides, floods, windstorms, etc., however ecological processes were effective at shaping disturbance effects in ways that allowed for adaptation and persistence of native fish. Restoration of ecological functioning across the landscape will be key to recovery and persistence of salmonids. Chinook salmon, along with other anadromous salmonids (steelhead, sockeye) and native resident fishes (such as bull trout) on the national forest evolved in a landscape with a high frequency of disturbance (Waples et al. 2008), as a result, Bisson et al. (2009) concluded that maximization of a habitat restoration program's effectiveness in promoting salmonid resilience may require a paradigm shift that focuses on working within the habitat's natural range of variability, in some cases abandoning unhistorical and arbitrary attempts to create pristine conditions at a landscape scale), acknowledging that, as a result of natural disturbance, historically not all habitat would have been pristine at the same time (Bisson et al. 2009). Waples et al. (2008) suggested that using management strategies that attempt to replicate disturbance regimes within the NRV would provide the best opportunity for resilience in Pacific salmon. The plan components (including desired conditions) in the revised forest plan were developed based on the historical natural range of variability found across the Nez Perce-Clearwater National Forest, and the use of prioritization tools such as multi-scale analysis in project development will enable identification, analysis, and minimization of effects of management activities on Chinook, steelhead, and other migratory salmonids. Implementation of the revised forest plan under all action alternatives is intended to eventually (at different paces under each alternative) lead to a mosaic of habitat conditions and natural processes across the national forest that attempt to replicate conditions (like opening size and hydrologic regime) that native fish evolved with and are adapted to. Replicating a natural range of conditions and improving connectivity will provide the best opportunity for species resilience in the future (Bisson et al. 2009). The aquatic plan components in the revised plan are intended to accomplish this in part by retaining and improving upon PACFISH and INFISH direction, in addition to incorporation of evaluating progress toward desired conditions into decision-making.

The revised Land Management Plan components are designed to be similarly protective for aquatic and riparian resources at the sub-watershed scale. Table 139 displays a crosswalk of standards and guidelines between PACFISH and INFISH and the Land Management Plan. Specifically, FW-STD-CWN-01 and FW-STD-WTR-04 are designed to require that, where aquatic and riparian desired conditions are not yet achieved, projects shall restore or not retard attainment of desired conditions. FW-STD-CWN-01 is designed to require that in Conservation Network Watersheds (CWNs) not meeting aquatic and riparian conservation strategy desired conditions, activities shall be designed and implemented in a manner that supports and contributes towards the recovery of federally listed species and the achievement of these desired conditions and does not retard them when evaluated at the HUC12 subwatershed scale. Desired conditions within the Land Management Plan are more extensive than PACFISH and INFISH Riparian Management Objectives. Desired conditions would be evaluated through the Stream Condition Indicator Assessment and multiscale analysis as explained in Appendix 4. Where desired conditions are not met, restoration actions will be implemented to move conditions toward desired conditions.

The need for updated guidance for forest activities is in part due to the changing threats to listed species recovery. For example, some climate projections suggest the emergence of new threats over the life of the plan. For example, temperature related pre-spawn mortality of adult salmonids could become increasingly problematic as climate change warms rivers, especially within marginal habitat, or at the geographic edge of species' ranges (Hinch et al. 2021, Bowerman et al. 2021). The establishment of the CWN is designed to help mitigate for this threat and increase resilience of salmonid populations on the Nez Perce-Clearwater over the life of the plan. Beechie et al. 2023 modeled threat severity and individual species response to restoration actions in the Chehalis River, and found that spring Chinook and Coho benefitted more from habitat restoration than steelhead and fall Chinook; however, targeting restoration to the areas with the most potential was beneficial to all species analyzed in the Chehalis River, and the reported increases in resilience could be expected by establishing cool water climate refugia even without additional restoration. The importance of basin specific analysis to inform restoration cannot be overstated. Part of the intent of the revised plan is to identify and focus on mitigating for future threats to Endangered Species Act listed species (such as temperature related adult mortality associated with climate change, which can be mitigated for in part with the cold water refugia areas like the CWN (Beechie et al 2023).This requires a transition from focusing on past threats that may not be as virulent now and in the future (such as sediment from roads, as this can now be largely mitigated by incorporating BMPs into project design). This underscores the need to focus on future threats. There is an urgent need to conduct projects within the framework provided by the revised plan, which looks forward in terms of expected threats, and contains clarified, updated, and strengthened plan components for aquatic species.

Salmonids that inhabit similar systems and have similar habitat requirements (that is, cold water, clean gravels, connected systems, and complex habitat) are likely to experience effects from management actions in similar fashion. This is particularly valid in the context of programmatic actions at the scale of a revised forest plan where no direct on-the-ground actions are proposed. This section therefore analyzes indirect effects of proposed actions to all listed aquatic species together just as the preceding section analyzed critical habitat physical or biological features (PBFs) for multiple species together. Management area (MA) allocations would be largely beneficial for all federally listed aquatic species in the action area. This is because one of the primary changes would be to increase recommended wilderness by over 60,000 acres so that a greater number of acres would be unsuitable for several activity types that otherwise could adversely affect listed species (for example, permanent road building) and greatly constrain others (for example, timber production); Refer to MA2-SUIT-RWILD plan components for complete suitability direction for recommended wilderness. While MA2 lands would technically shrink by 22,658 acres and be converted to MA3 lands, this would not represent greater opportunity for adverse actions because the shift from MA2 to MA3 lands is largely the result of proposing fewer rivers for wild and scenic status; the number of rivers eligible for wild and scenic river designation would decrease from 29 under the 1987 plan to 12 under the proposed plan (11 suitable and 1 eligible). However, stream and riparian protections would not be compromised because the quarter-mile protection corridor (cumulatively equates to the 22,658 acres that would change from MA2 to MA3) afforded by the National Wild and Scenic Rivers System Act is larger than necessary to protect stream functions such that the proposed riparian management zone (RMZ) distances would offer sufficient protection as determined by PACFISH and INFISH. Furthermore, RMZ plan components provide guidance for management activities to re-establish disturbance patterns in areas where it is lacking to restore riparian processes according to proposed RMZ desired conditions (FW-DC-RMZ-01, 02).

Identifying areas for suitability of motorized and non-motorized access proposals have the potential to adversely affect listed species because lands suitable for motorized use are proposed to increase (pending likely future travel management decisions) for both summer (45 percent to 55 percent) and winter (39 percent to 60 percent); Roads and trails that support motorized use can cause sedimentation and large woody debris issues if not hydrologically disconnected. However, proposed standards and guidelines are expected to mitigate these effects. For example, FW-STD-ARINF-01 says: “Road maintenance and new road construction shall be designed to minimize adverse effects to threatened, endangered, proposed, or candidate aquatic species and their habitat,” and FW-GDL-ARREC-02 says: “To reduce potential adverse effects to water quality and aquatic resources, construction of new facilities or infrastructure within floodplains should be avoided. Where new activities inherently must occur in riparian management zones (for example, at road and trail stream crossings, boat ramps, or docks), they should be located and designed to minimize adverse effects to floodplains and other riparian-dependent resource conditions (for example, within geologically stable areas and avoiding major spawning areas).” These standards and guidelines would be expected to ensure that if adverse effects to listed species were to occur in the future as the result of these motorized access suitability proposals, they would be minor and not preclude species’ recovery to a non listed status.

Aquatic and riparian management strategies in the proposed forest plan would be beneficial for Federally listed species as several RMZ and Conservation Watershed Network (CWN) plan components were specifically designed to maintain the intent of PACFISH and INFISH direction (for example, FW-RMZ-STD-07); the same direction that was largely responsible for passive restoration and upward trend in habitat conditions documented by the PACFISH and INFISH Biological Opinion (PIBO) program. Unlike the focus on passive restoration under the 1987 Forest Plan, the revised forest plan includes components that also emphasize active restoration. For example, FW-OBJ-RMZ-01 says: “Improve 300 to 700 acres of riparian habitat every 5 years, through improvements that are intended to meet desired conditions for riparian management zones, such as road obliteration, riparian planting, hardwood restoration, post assisted log structures, beaver dam analogs, and reconnecting floodplains by removing road prisms or berms.” This increased capacity for active restoration has the potential to have long-term beneficial effects to all listed species. Identifying inner and outer zones of riparian management zones (RMZs) that clearly allow for active restoration to occur where desired conditions are not currently being met as opposed to PACFISH and INFISH that was often interpreted as “exclusion zones” or areas that were not readily available for active management.

Indirect effects of proposed actions such as the monitoring program, potential management approaches, and other plan content would also be beneficial for listed species, as these elements are designed to facilitate implementation of the new forest plan. Because the net effect of most other proposed actions as described above are beneficial, proposals to evaluate progress towards meeting desired conditions and engage in partnerships, establish priority watersheds, etc. would likewise have beneficial effects all listed species.

The net effect of actions under the plan is one that promotes recovery of listed fish through a combination of passive and active management, while allowing actions with short-term adverse effects. Adverse effects are not expected to hinder progress of critical habitat or listed fish toward recovery due to the management constraints imposed by plan components that protect fish and critical habitat. The primary reason for this is the inclusion of desired conditions that identify what future projects would be designed to achieve. For example, projects in watersheds that contain listed species would have to “contribute to and enhance the conservation of aquatic species of conservation concern and recovery of threatened or endangered fish species” (FW-DC-CWN-01); “provide habitat that supports robust native fish populations, which are able to expand to and recolonize adjacent unoccupied habitats” (FW-DC-CWN-02); and ensure “critical habitat components (primary biological features) provide the ecological conditions necessary to achieve species recovery.

Spawning, rearing, and migratory habitat are widely available and inhabited. Listed aquatic species have access to historic habitat and appropriate life history strategies (for example, bull trout resident, fluvial, adfluvial, and anadromy) are supported" (FW-DC-WTR-10). It is important to note that while some plan components could temporarily have adverse effects to listed species (for example, FW-OBJ-TBR-01: Offer 190-210 million board feet timber per year.), those components would have to be implemented in a way that does not compromise the above-mentioned desired conditions.

See Table 140 for the alternatives and summary of expected effects for individual Endangered Species Act listed fish species.

Species of Conservation Concern

Pacific Lamprey

Under the Pacific Lamprey Conservation Initiative, a conservation agreement was signed by numerous tribes, states, and federal agencies, including the Northern Region of the Forest Service. As part of this effort, 18 regional management units (RMUs) were developed, and each developed a regional implementation plan. The Nez Perce-Clearwater falls within the Snake River RMU. Every five years, an assessment is completed by the U.S. Fish and Wildlife Service for each RMU. In addition, regional implementation plans are updated annually to identify, prioritize, and implement key conservation actions. The most recent Snake River implementation plan is problematic in that it makes several claims about lamprey abundance and threats but does not include citations or data to support these claims. As such, this document will consider the claims and threat ratings made in that document but will also include discussion of relevant data from other sources.

Pacific lamprey have experienced declines on the Nez Perce-Clearwater, which have been primarily attributed to adult passage concerns at mainstem Snake and Columbia dams downstream of the national forest. These declines led the Nez Perce Tribe to conduct trapping at mainstem Columbia River dams and translocations to streams both within and outside of the national forest beginning in 2007 (Hess et al. 2022). This action has resulted in increases of juvenile lamprey on the national forest. Issues traditionally related to forest land management such as stream passage, dewatering, water quality, stream and floodplain degradation all received low to insignificant threat scores for streams on the Nez Perce-Clearwater in the 2018 assessment by the U.S. Fish and Wildlife Service (USFWS), with the exception of the South Fork of the Clearwater and Lower Clearwater, which received medium threat ratings for stream and floodplain degradation in the 2018 assessment. The latest Snake River Lamprey Regional Implementation Plan (Lamprey Technical Workgroup 2022), updated in 2022, elevated floodplain degradation, dewatering and flow management, and water quality to high severity threats in the lower Clearwater, presumably because of an expansion in the analysis area to include the Potlatch River. The Potlatch basin was previously excluded from the analysis because lamprey were considered extirpated in that drainage (Hyatt et al 2006). The Nez Perce Tribe introduced lamprey to the Potlatch River in 2021 and are continuing supplementation efforts there. Across the Nez Perce-Clearwater, the highest rated threats to lamprey were related to effects that occur primarily beyond the scope of forest management, such as mainstem dam passage, lack of awareness, climate change, and small population size. The Forest Service, with partners, has recently completed four projects in the South Fork Clearwater that are expected to be beneficial to lamprey, in addition to one project in the Lower Clearwater in the Potlatch River drainage. In addition, the Potlatch basin currently has a very active stream restoration program led by the Latah Soil and Water Conservation District, so conditions for lamprey are expected to continue to improve as a result of active restoration.

Predation, by both native northern pikeminnow and non-native smallmouth bass was referenced as a threat in the USFWS 2018 Assessment. Predation was changed in 2022 in the Regional Implementation Plan to a high-level threat in the Lower Salmon River, and a moderate threat in the Lower Clearwater. The elevation of threat in the lower Clearwater was reported as part of an ongoing revision by the technical workgroup relating to warm-water fish present in the Potlatch River (John Erhardt USFWS, personal communication). This is somewhat confusing, as Idaho Department of Fish and Game inventoried the Potlatch River basin in 2003 and 2004, and found that the system primarily contained cold-water species, and that most abundant warm water fish (41 percent numerically) was dace. They did not report smallmouth bass but did report that 0.3 percent of the catch numerically was largemouth bass and that 0.1 percent of the catch numerically was northern pikeminnow (Bowersox and Brindza 2006). There is no literature or data that identify dace as a predator of lamprey. The lower Salmon River does contain smallmouth bass, however literature that identifies them as a threat to lamprey is sparse. Arakawa and Lampman (2020) tested predation rates of 10 native and non-native species on larval lamprey and reported that benthic feeders like carp and sturgeon were more efficient predators of larval lamprey than bass and pikeminnow, and that sediment provided refuge from consumption from bass. Schultz et al. (2017) did document lamprey predation by smallmouth bass in a small stream in Oregon, but only found lamprey in 6.2 percent of bass stomachs and had a limited (number = 303) sample size. In a series of recent studies published by U.S. Geological Survey that included almost 23,000 smallmouth bass stomach samples from the Snake River over several years, lamprey were not identified as a major diet item for smallmouth bass, even though intensive sampling occurred during spring and overlapped with juvenile lamprey outmigration timing (Erhardt et al. 2018, Hemingway and Tiffan 2021, Tiffan et al. 2020). This is not surprising, as out migrating juvenile lamprey in mainstem rivers and impoundments tend to move at night and in very deep water (CPUD 2000 in Groves et al. 2001), which would provide temporal and spatial separation from most suspected piscine predators. Additionally, the previous discussion of the capability of juvenile mortality to affect population size in fish with a type-3 survivorship curve applies to lamprey as well. The low proportions of lamprey in diet samples of predators in the literature fail to make the case for anything other than natural compensatory mortality. Given the lack of scientific information documenting prevalence of bass and pikeminnow in the Potlatch River, the lack of literature demonstrating a clear population level threat to lamprey from predators, and the lack of a clearly articulated rationale for the threat increase, the increased predation threat in the 2022 Regional Implementation Plan may be unwarranted. An updated species status assessment in expected to be released soon by the Lamprey workgroup, and it may contain more detailed documentation of changes to threats. The forest looks forward to continuing to work with cooperators in the Lamprey workgroup.

There is a great deal of uncertainty about the cause of recent declines in lamprey passage at large hydropower projects, and what can be done to reverse it. Using dam passage to estimate abundance is problematic for several reasons. It is important to note that most adult lamprey pass hydropower facilities at night (Keefer et al. 2013), and many fish find passage routes through the dam that avoid detection. In addition, data on night counts is not accessible via Data Access in Real Time (DART) or the Fish Passage Center, (FPC), so daytime counts are often cited by researchers, but must be interpreted cautiously, as they can only be used as a relative index of passage. Annual daytime lamprey counts at the Lower Snake Dams since 1999 are shown in Figure 55. Lower Granite Dam began day counts of lamprey in 1999. Annual day lamprey counts are useful for comparing passage between dams, and for examining trends over time, but are not suitable for abundance estimates, for several reasons, including that passage monitoring timing and effort have not been consistent across years. Annual adult day lamprey counts at all Snake River dams were highly synchronous and variable from 1999 to 2022. The destination of lamprey not detected at each upriver dam is unknown and should not be automatically assumed to represent mortalities because some fish may have stopped migrating or found adequate spawning habitat. In the only study of the fate of adult lamprey migrating past large dams on the Columbia River, Noyes et al (2015) reported survival estimates of 68 to73 percent for the three-year study, and that 12 to 27 percent of lamprey entered reservoir tributaries to spawn. In addition, if fish not detected at upriver dams are indeed mortalities, the cause of those mortalities has yet to be documented, and there are a range of possibilities, including predation of adults. Although adult lamprey are large enough to avoid most freshwater piscine predators, exceptions exist. For example, lamprey are a preferred diet item for adult white sturgeon which reside in the Lower Snake and Columbia rivers. Adult lamprey can undergo very heavy predation pressure. In a study in Europe, 80 percent of tagged adult sea lamprey (*Petromyzon marinus*) were consumed by European catfish (*Silurus glanis*), a very large non-indigenous catfish (Boulêtreau et al. 2020). Until there is less uncertainty around the fate of adult lamprey migrating up the Columbia and Snake rivers, dam counts should only cautiously be used as an index of abundance, with an acknowledgement that the mechanism for the observed decreasing passage at subsequent upstream dams is unknown. From 2009 to 2017, 24-hour passage at Lower Granite Dam (the last dam that fish pass on the way to the Nez Perce-Clearwater) increased, with sharp declines observed from 2017 to 2020 and a slight increase in 2021 (Erhardt et al. 2022).

There are several recent studies that are attempting to address knowledge gaps in lamprey assessment and conservation. A recent novel study at Lower Granite Dam on juvenile lamprey passage used hydro-acoustics to investigate passage routes and passage success of juvenile lamprey through a large hydropower project (PNNL 2023). Conservation efforts for lamprey are just beginning to be implemented on a larger scale, with several assessments and implementation plans published in just the last five years, with the first edition of best management guidelines published in 2020 by the U.S. Fish and Wildlife Service (Lamprey Technical Workgroup 2020).

Young et al. (2022) recently conducted and published a whole-basin assessment of Pacific lamprey distributions derived from eDNA sampling. They reported that there were 1,165 miles of river occupied by Pacific lamprey in the Upper Snake River basin (including the Clearwater and Salmon rivers). They reported positive eDNA detections at and above adult translocation sites, as well as in reaches with no translocations. They cited their own data, as well of that of Clemens et al (2017), to conclude that “access to and availability of suitable upriver and tributary spawning habitat is not limiting Pacific lamprey populations in this this region”. The notion of instream conditions not being limiting to lamprey on the national forest is supported by project data that have documented areas of high lamprey abundance. For example, during a bridge replacement activity during the Colette Mine rehab in 2014 on Lolo Creek that involved dewatering the channel temporarily, extremely high densities of juvenile lamprey were observed, and 2,983 juvenile lamprey were relocated from just the immediate vicinity of the project by the Forest Service and partners for that project.

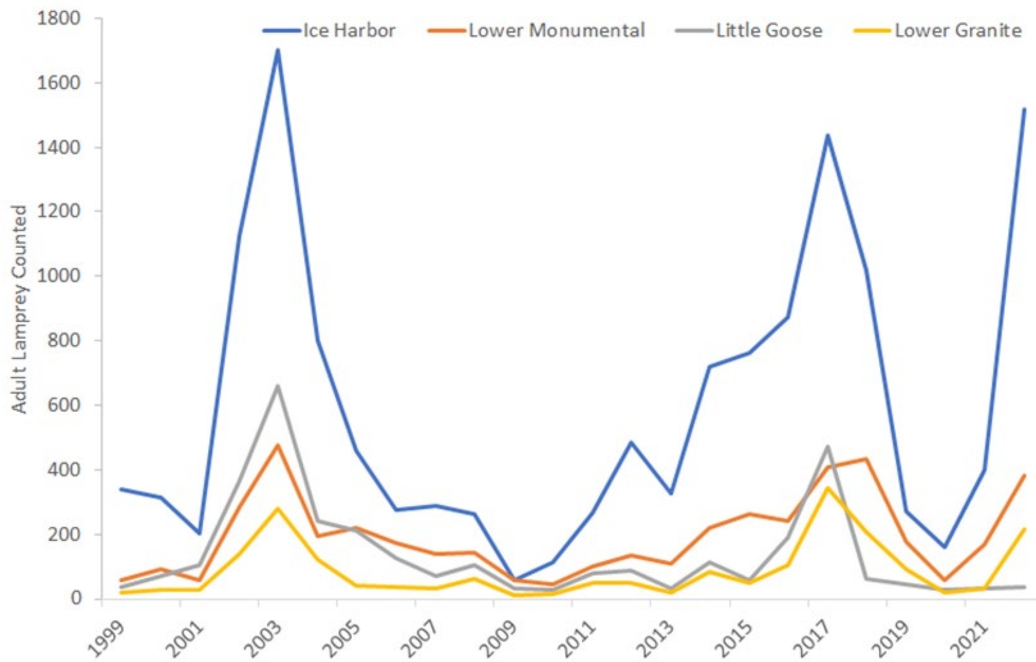

Figure 55. Adult Pacific lamprey passage (daytime counts) at Lower Snake River Dams from 1999 to 2021. Data from University of Washington Data Access in Real Time (DART).

The aquatic ecosystem plan components, the establishment of the Conservation Watershed Network (CWN), the identification of priority watersheds, are expected to be beneficial to lamprey on the national forest, and to provide the ecological conditions to maintain population viability.

Regional Forester's Sensitive Species List

Fish

The 2011 sensitive species list includes Pacific lamprey See above discussion under Species of Conservation Concern heading for lamprey. It also included Westslope cutthroat trout, redband trout and Clearwater Sping/Summer Chinook. For these species, see additional discussion under the Affected Environment-Aquatic Species section of this document..The aquatic and riparian plan components in the Land Management Plan are expected to adequately provide the ecological conditions for long term persistence of these species within the plan area.Mollusks

Both the Western ridged mussel and the Western pearlshell mussel are included on the current regional forester's sensitive species list. Although several West Coast states have reported enigmatic mass mortality events for Western ridged mussels, the most recent surveys by Idaho Department of Fish and Game indicate that they are widespread and abundant within their historic range on the Nez Perce-Clearwater. In addition, the most recent Western pearlshell mussel surveys by the U.S. Fish and Wildlife Service on the national forest reported some of the highest densities and numbers of Western pearlshell mussels ever reported in the literature. According to the most recent information, both species of mussel have secure populations on the national forest. This could be due to protective land allocation afforded by wilderness and roadless designations, as well as the protective measures (PACFISH and INFISH) that exist under the current forest plans. Because the aquatic plan components carry forward the protections afforded by PACFISH and INFISH, it is expected that ecosystem plan components that are designed to protect water quality and habitat for other aquatic species will be sufficient to protect habitat and water quality for mussels. Because the types of actions that would be allowed under the new plan are not different between action alternatives, and because the difference between alternatives are primarily pace and scale, management under the action alternatives are expected to have similar effects to mussels. As a result, it is expected that the revised forest plan will continue to provide for the continued persistence of these two mussel species on the Nez Perce-Clearwater. An additional plan component specific to mussels (FW-GDL-WTR-07) is designed to conserve existing Western ridged and Western pearlshell mussel populations on the national forest, by suggesting that individuals should be re-located to an alternative site with suitable habitat prior to de-watering channel work proposed in areas containing habitat for these species. This is a continuation of a practice that currently occurs on the national forest.

Insects

None of the aquatic insects that were evaluated were included on the Species of Conservation Concern list. Two (the Lolo Mayfly and the Rocky Mountain Refugium Caddisfly) are on the regional forester's sensitive species list as "may occur in the plan area." If present, it is not expected that any of the alternatives will have any long-term deleterious impacts on them. Most of the aquatic insect observations are in areas that are primitive wilderness areas and not subject to the types of management actions that would be expected to affect water quality and habitat. Although they may undergo short term impacts from potential natural disturbances, they have evolved and persisted under a natural disturbance regime. For those aquatic insects that were observed outside of the designated wilderness areas, that would potentially be in areas where active management would take place, it is expected that ecosystem plan components designed to protect water quality and habitat for other aquatic species will be sufficient to protect habitat and water quality for aquatic insects. Because the types of actions that would be allowed under the new plan are not different between alternatives, other than the No Action Alternative, and because the difference between alternatives are primarily pace and scale, management under the action alternatives are expected to have similar effects to aquatic insects; effects would just occur at different rates. Table 140 summarizes the effects of all alternatives to native aquatic species previously identified as at-risk or of public interest, along with rationale.

Table 139. PACFISH/INFISH planning, coordination, project implementation standards and guidelines crosswalk with Land Management Plan standards and guidelines

PACFISH/INFISH	Land Management Plan
WR-1. Design and implement watershed restoration projects in a manner that promotes the long-term ecological integrity of ecosystems, conserves the genetic integrity of native species, and contributes to attainment of riparian management objectives. WR-3 PACFISH ONLY: Do not use planned restoration as a substitute for preventing habitat degradation (that is, use planned restoration only to mitigate existing problems, not to mitigate the effects of proposed activities). FW-1. Design and implement fish and wildlife habitat restoration and enhancement actions in a manner that contributes to attainment of the riparian management objectives. WR-2. Cooperate with federal, state, local, and tribal agencies, and private landowners to develop watershed-based Coordinated Resource Management Plans (CRMPs) or other cooperative agreements to meet riparian management objectives. FW-2. Design, construct, and operate fish and wildlife interpretive and other user-enhancement facilities in a manner that does not retard or prevent attainment of the Riparian Management Objectives or adversely affect listed anadromous and inland native fish. For existing fish and wildlife interpretive and other user-enhancement facilities inside Riparian Habitat Conservation Areas, assure that Riparian Management Objectives are met and adverse effects on listed anadromous and inland native fish are avoided. Where Riparian Management Objectives cannot be met or adverse effects on listed anadromous and inland native fish avoided, relocate or close such facilities. FW-3. Cooperate with federal, tribal, and state wildlife management agencies to identify and eliminate wild ungulate impacts that prevent attainment of the Riparian Management Objectives or adversely affect listed anadromous and inland native fish. FW-4. Cooperate with federal, tribal, and state fish management agencies to identify and eliminate adverse effects on native fish associated with habitat manipulation, fish stocking, fish harvest, and poaching. RA-1. Identify and cooperate with federal, tribal, state, and local governments to secure instream flows needed to maintain riparian resources, channel conditions, and aquatic habitat. LH-4. Use land acquisition, exchange, and conservation easements to meet Riparian Management Objectives and facilitate restoration of fish stocks and other species at risk of extinction.	FW-STD-CWN-01. In Conservation Network Watersheds not meeting aquatic and riparian desired conditions, activities shall be designed and implemented in a manner that supports or contributes towards the recovery of federally listed species and the achievement of these desired conditions and does not retard them when evaluated at the HUC12 subwatershed scale. Short-term adverse effects from project activities may occur when they support the long-term recovery of aquatic and riparian desired conditions and federally listed species. FW-STD-WTR-02. Project-specific best management practices (BMPs), including both federal and state BMPs, shall be incorporated into project planning as a principal mechanism for controlling non-point pollution sources, to meet soil and watershed desired conditions, and to protect beneficial uses. FW-STD-WTR-04. Where aquatic and riparian desired conditions are being achieved, projects shall maintain those conditions. Where aquatic and riparian desired conditions are not yet achieved, and to the degree that project activities would contribute to those conditions, projects shall restore or not retard attainment of desired conditions. Short-term adverse effects from project activities may occur when they support the long-term recovery of aquatic and riparian desired conditions and federally listed species. Exceptions to this standard include situations where Forest Service authorities are limited (1872 Mining Law, state water right, etc.). In those cases, project effects shall not retard attainment of desired conditions for watersheds, to the extent possible within Forest Service authorities. FW-STD-WTR-06. To restore watersheds, management activities in watersheds with approved total maximum daily loads should be designed to comply with the total maximum daily load allocations following project implementation.

Table 140. Effects summary for aquatic at-risk species and species of public interest

Species	Status	Effects summary
Snake River sockeye salmon	Endangered	No Action Alternative: Current management does not usually affect this species, since their distribution is limited to the mainstem Salmon River, and they do not spawn or rear in areas in or adjacent to the Nez Perce-Clearwater. The Salmon River is a migration corridor to their spawning and rearing habitat. Activities such as boat ramp construction and maintenance may result in short-term effects to individual fish, although activities are scheduled to avoid migration timing.
Snake River sockeye salmon	Endangered	Alternatives: W, X, Y, Z, and Preferred: Effects would be indistinguishable from No Action Alternative.
Snake River fall Chinook salmon	Threatened	No Action Alternative: Current management affects this species when projects add cumulatively to mainstem river sediment and temperature conditions. Generally, these effects are immeasurable.
Snake River fall Chinook salmon	Threatened	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be indistinguishable from No Action Alternative. These alternatives are not expected to result in cumulative mainstem effects that exceed those under No Action Alternative.
Snake River spring and summer Chinook salmon	Threatened (Salmon Basin)	No Action Alternative: Risk of effect is limited to projects in the Salmon basin only. Current management has resulted in short-term adverse effects to habitat and individual fish. Long term, stream habitat is static or improving based on PACFISH and INFISH Biological Opinion (PIBO) monitoring. Number of returning wild-origin adult salmon has both declined and improved in the past 5 years, due to many reasons that occur out-of-basin.
Snake River spring and summer Chinook salmon	Threatened (Salmon Basin)	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be indistinguishable from the No Action Alternative. The Conservation Watershed Network in the Salmon basin was in part based on major and minor salmon spawning areas. The Conservation Watershed Network has enhanced protection specified in components along with prioritized aquatic restoration. The components are expected to support salmon recovery efforts and recovery plan goals. Improving trends in habitat condition on the national forests are expected to continue. Projects could result in short-term adverse effects to habitat and individual fish, but to no greater degree than No Action Alternative.

Species	Status	Effects summary
Snake River steelhead	Threatened	No Action Alternative: Risk of effect is widespread and exists across most of Forests' land base, excluding the North Fork Clearwater upriver of Dworshak Dam and the Palouse subbasin. Current management has resulted in static or improving stream conditions. Improving conditions are noted in areas critical for steelhead spawning and early rearing in the Lochsa, Selway, Lower Salmon, and South Fork Clearwater subbasins, based on PIBO monitoring. Some projects have resulted in short-term adverse effects to habitat and individual fish, but long-term, conditions are either static or improving. Number of returning wild-origin adult steelhead has both declined and improved in the past 5 years, due to many reasons that occur out-of-basin.
Snake River steelhead	Threatened	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be indistinguishable from the No Action Alternative or result in improved outcomes. The Conservation Watershed Network was in part based on major and minor salmon spawning areas for steelhead and critical habitat, particularly in the Clearwater basin outside of the North Fork. The Conservation Watershed Network has enhanced protection specified in components along with prioritized aquatic restoration and recognizes the importance of national forest lands in the Clearwater basin in recovery of steelhead. The components are expected to support steelhead recovery efforts and recovery plan goals. Improving trends in habitat condition on the national forests are expected to continue where they are presently occurring, including those in the Lochsa, Selway, Lower Salmon, and South Fork Clearwater subbasins. Components are intended to support improving habitat trends in the national forest portions of the Lower Clearwater that include steelhead designated habitat. While long-term improvements are expected, projects could result in short-term adverse effects to habitat and individual fish, but to no greater degree than No Action Alternative and possibly less, given greater stringency and clarification of components.

Species	Status	Effects summary
Columbia River bull trout	Threatened	No Action Alternative: Risk of effect is widespread and exists across most of Forests' land base, excluding streams in the Palouse subbasin. Current management has resulted in static or improving stream conditions, except for the Upper North Fork Clearwater. PIBO data for this subbasin indicates a downward trend. This area of the national forests supports habitat critical for recovery of bull trout in Idaho. It contains high elevation streams with the most miles of stream reaches modeled at high probability for bull trout occupancy in the 2040 Climate Shield (Isaak et al. 2015). It currently supports extensive spawning and early rearing of fluvial and adfluvial bull trout. Both statewide and within the Clearwater basin, Idaho Department of Fish and Game has documented positive trends in number of bull trout since the early 1990s.
Columbia River bull trout	Threatened	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be indistinguishable from the No Action Alternative, but additional investigation is needed to confirm if the downward trend the Upper North Fork Clearwater is sustained, and identify what management actions, if any, have contributed. Several streams with documented bull trout spawning and early rearing in this subbasin are included in the Conservation Watershed Network. Aquatic components were developed in part to address this situation and would be expected to result in projects reversing any downward trend over the long term. Elsewhere on the national forests, improving trends in habitat condition are expected to continue where they are presently occurring, including those in the Lochsa, Selway, Lower Salmon, and South Fork Clearwater subbasins. While static conditions or long-term improvements are expected, projects could result in short-term adverse effects to habitat and individual fish, but to no greater degree than No Action Alternative and possibly less, given greater stringency and clarification of components.

Species	Status	Effects summary
Pacific lamprey	Species of Conservation Concern	No Action Alternative: Pacific lamprey are critically imperiled in the State of Idaho. The species is not addressed in the 1987 Forest Plans and has no components that speak directly to it. It is assumed the existing static and improving habitat conditions indicated by PIBO and Forest Plan monitoring data benefit lamprey as well. Risk of effect is widespread and exists across most of Forests' land base, excluding the North Fork Clearwater upriver of Dworshak Dam and the Palouse subbasin. While there are no components that address lamprey, recent in-channel habitat restoration projects have recognized the importance of lamprey and surveyed for them before de-watering streams. Where found, individuals have been re-located. Where these actions are not taken, it is likely that individual lamprey will be adversely affected if they are present in areas de-watered during project implementation.
Pacific lamprey	Species of Conservation Concern	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be fewer under these alternatives compared to the No Action Alternative because a component specifically addressing lamprey conservation (FW-GDL-RMZ-10) while conducting in-channel work is included. All the other aquatic components are expected to protect and enhance lamprey by supporting improving trends where they exist and initiating trends where they don't, particularly in the Conservation Watershed Network. The Conservation Watershed Network was in part based on sub-watersheds known to be important for lamprey. It is thus unlikely that these alternatives will result in projects causing adverse effects to lamprey. Like other aquatic species, short-term adverse effects to habitat could occur, but to no great degree than No Action Alternative and possibly less, given greater stringency and clarification of the components.
Westslope cutthroat trout	Sensitive Species List	No Action Alternative: Westslope cutthroat trout are widely distributed across the Nez Perce-Clearwater and provide renowned sport fisheries in mainstem rivers and larger tributaries. Risk of effect is widespread and exists across most of Forests' land base. Like other salmonid species on the national forests, current management has resulted in static or improving stream conditions. Some projects have resulted in short-term adverse effects to habitat and individual fish, but long-term, conditions are either static or improving.

Species	Status	Effects summary
Westslope cutthroat trout	Sensitive Species List	Alternatives: W, X, Y, Z, and Preferred: Effects are expected to be indistinguishable from No Action Alternative. The Conservation Watershed Network watersheds include habitats providing extremely important spawning and early rearing habitat for Westslope cutthroat trout, plus two subwatersheds supporting resident, allopatric Westslope cutthroat populations with known high genetic integrity (Moose Creek and Meadow Creek within the Selway subbasin). Improving trends in habitat condition on the national forests are expected to continue where they are presently occurring, including those in the Lochsa, Selway, Lower Salmon, and South Fork Clearwater subbasins. Components are intended to support improving habitat trends where they are not known to exist. While long-term improvements are expected, projects could result in short-term adverse effects to habitat and individual fish, but to no greater degree than No Action Alternative and possibly less, given greater stringency and clarification of components.

FW-STD-WTR-04 requires that where aquatic and riparian desired conditions are being achieved, projects shall maintain those conditions. Where aquatic and riparian desired conditions are not yet achieved, and to the degree that project activities would contribute to those conditions, projects shall restore or not retard attainment of desired conditions. FW-STD-WTR-04, as part of all action alternatives, carries forward the same expectation from PACFISH, using language consistent with the 2012 Planning Rule and eliminating the word "interim." The expectation that actions on the Nez Perce-Clearwater will not result in permanent, long-term degradation of aquatic habitat that is essential for aquatic species, is the same for all alternatives. Therefore, outcomes from Alternatives W, X, Y, Z, and the Preferred would be expected to be indistinguishable from those in the No Action Alternative.

Cumulative Effects

Adjacent Land and Other Management Plans

The Nez Perce-Clearwater encompasses the headwaters of nearly all watersheds flowing through and out of National Forest System lands. While there are inholdings of private lands within the Nez Perce-Clearwater boundaries and small communities, such as Elk City and Dixie, no major landowner or federal agency manages lands on a broad scale upstream of National Forest System lands. For the most part, stream systems on the Nez Perce-Clearwater originate on the national forest in protected headwaters and eventually flow downstream onto lands owned or administered by entities other than the Forest Service, ultimately flowing into the Lower Granite Reservoir on the Snake River. Many fish populations, whether they move off the national forest as part of their life cycle or remain entirely within a localized area, require interconnectivity of these streams to survive as a population. For almost all species, genetic interchange between subpopulations is necessary to maintain healthy fish stocks. The more wide-ranging a species is, the more critical interconnectivity may be for the fish to be able to access important habitat components.

Thus, activities off of the national forest that affect other stages of a fish's life history or migration corridors can have significant impacts to fish populations upstream. For anadromous fish, these include cyclic changes in ocean conditions, commercial and sport harvest, predation on juvenile and adult salmonids, operation of mainstem dams on the Snake and Columbia rivers, success of hatchery programs included in evolutionary significant units (ESUs), and potential effects from climate change. Therefore, the cumulative effects to consider include those that could be added to any effects the Nez Perce-Clearwater managers may have on lands downstream, and in the case of anadromous fish, out-of-basin effects to threatened or endangered populations. The recovery plans for Endangered Species Act (ESA) listed species published by U.S. Fish and Wildlife Service and National Marine Fisheries Service consider all of these types of cumulative effects on an ongoing basis, and update threats to listed species in their 5-year reviews. Threats change over time as status of populations change, threats are addressed, and new threats emerge. The national forest will continue to rely on recovery plans and 5-year status updates in ESA consultation for projects initiated under the revised forest plan. This coordination will ensure that projects on the national forest are considering the latest and best available scientific information during implementation of the revised plan. In addition, any activities that are conducted by the federal government or that have a federal nexus are not expected to have ESA cumulative effects, because these activities would be subject to Section 7 ESA consultation.

Bureau of Land Management (BLM) lands occur downstream of and, in many cases, immediately adjacent to National Forest System lands, particularly in the Lower Salmon and Lower Little Salmon subbasins. Activities occurring on BLM lands include but are not limited to timber harvest, livestock grazing, mineral development, and recreation. The BLM manages many recreation sites within the Salmon River corridor, including camping areas and boat ramps. These lands are managed under a management plan similar to forest or land management plans. The Bureau of Land Management (BLM) plan for areas adjacent to or downstream of the Nez Perce-Clearwater was revised in the past decade. The aquatics components in this plan are similar to PACFISH and INFISH. Under all alternatives, management of National Forest System lands upstream from BLM lands is not expected to affect implementation of the BLM or its ability to design and implement projects or manage recreation, nor is management of other federal lands expected to affect management on the Nez Perce-Clearwater national forest.

The action alternatives are expected to support recovery goals for threatened and endangered fish and support goals outlined in the plans highlighted in the State and Local Plans Section of this document. These include Idaho Department of Fish and Game's Five-Year Management Plan, State Wildlife Action Plan, and the Nez Perce Tribe Fisheries Management Plan, CRITFIC's Lamprey Plans. While complete restoration of all degraded habitat on the Nez Perce-Clearwater alone will not recover Endangered Species Act (ESA) listed anadromous fish or bull trout, actions that move conditions toward the desired conditions described in the revised forest plan are necessary to support and enhance recovery efforts both on the national forest and downstream. Recovery of bull trout and ESA listed anadromous fish cannot be fully supported without high quality spawning and rearing, and migration habitat provided in waters of the Nez Perce-Clearwater.

A host of activities occur on private lands within both the Clearwater and Salmon basins. These include water diversion, irrigation, livestock grazing, farming with varied crops, timber harvest, hunting, outfitted and non-outfitted angling, construction of subdivisions, housing, and commercial development, building and stocking of private fishponds, chemical treatment of noxious weeds, flood control, and stream channel manipulation. These activities all occur under the umbrella of state or federal regulation and permitting. The state, through agencies like the Idaho Department of Fish and Game or the Idaho Department of Lands, as well as the Nez Perce Tribe and federal agencies like the U.S. Department of Agriculture Natural Resource Conservation Service provide administration and oversight of these activities through the appropriate laws and management plans discussed earlier in this document. The administration of these state and federal programs is not expected to affect implementation of the revised forest plan, nor is implementation of the revised forest plan expected to have significant effects on these agencies' implantation of their plans and stewardships.

According to a recent Biological Opinion for hatchery steelhead programs in Idaho:

"*The Idaho Department of Lands is pursuing an ESA section 6 cooperative agreement. The intent is to develop forest management practices that would better protect aquatic habitat for ESA-listed fish. This forestry program, if approved, would apply to forestry management and timber harvest on state and private lands (voluntary) in the Salmon and Clearwater River Subbasins in Idaho*" (NMFS, 2020).

It is expected that this effort would be complementary with the land management plan and would provide benefit to listed species that occur on the forest.

As previously described, the Aquatic Ecosystems plan components are common to all action alternatives. The effects conclusions for these components indicated that they would be indistinguishable from those in the No Action Alternative or result in neutral or improved long term outcomes for riparian, aquatic habitat, and aquatic species. However, with the differences in pace and scale of restoration associated with each action alternative, there is an increase in risk as pace and scale increase between alternatives. This is because although plan components are intended to protect aquatic habitat and species, an increase in any activity could increase the risk that something could go wrong. An example of this could be if an accident caused an increase of sediment to wash into a stream, it is an acknowledgement that with increased activity comes increased risk. However, even if occasional mishaps occur, it is expected that they would be the exception. Therefore, substantial changes in the quality of water flowing, including sediment and temperature, on National Forest System lands are not expected and any changes in the populations of aquatic species are expected to result in improved conditions off of the national forest.

Climate Change

General climate change effects on fish

Predicting what effects future climatic changes may have on fish relies on complex climate change models. One of the difficulties associated with anadromous fish like salmon and steelhead, and highly migratory fish like bull trout, is understanding how climate affects all of the habitats that the fish use during different portions of their lives. In addition, climatic effects are expected to be different for various fish species, and effects that are detrimental to one species may be beneficial to another (Lynch et al. 2016). This section is not intended to be an exhaustive review or analysis of climate science. However, it is important to highlight some of the effects expected to occur on fish that rely on habitat within the boundaries of the Nez Perce-Clearwater. Climate modeling has suggested four general effects that are likely to occur relating to streams on the national forest. These are more of the annual precipitation will be rain, there will be less snowpack, there will be higher and earlier peak flows, and stream temperatures will rise (Crozier and Zabel 2006, Northwest Power and Conservation Council et al. 2007, Bisson et al. 2008, Isaak et al. 2012, Williams et al. 2015). These effects are likely to directly and indirectly affect multiple primary constituent elements (PCEs) or physical or biological features (PBFs), especially those related to flow and temperature (5, 7, 9). Most models of climate effects on fish make predictions at multiple temporal scales, with various target years as well (2080, 2090, etc.), but since the forest plan is intended to guide management for the next 15 years, the 20- to 40-year predictions are most relevant to this document. Climate vulnerability assessments that account for a species' exposure, sensitivity, and adaptive capacity are more robust (Wade et al. 2017, Wade et al. 2016) and are given preference in this section. A recent climate change vulnerability assessment from National Oceanic and Atmospheric Administration Fisheries characterized all evolutionary significant unit and distinct population segment groups of salmon and steelhead in the coterminous western United States based on both the population's vulnerability (exposure and sensitivity) to climate change, as well as its adaptive capacity or resilience (Crozier et al. 2019).

Bull Trout

Bull trout require the coldest water of any of the listed fishes on the Nez Perce-Clearwater. This is especially true for embryos and juveniles (Isaak, Wenger, and Young 2017). For this reason alone, they are thought to be highly sensitive to changes in climate. However, they also express multiple life history strategies on the national forest that may increase population resilience. Isaak et al. (2017) observed that although they have suffered range contraction in many locales (Eby et al. 2014), no populations have yet gone extinct due to climate change. Many of the streams on the national forest have been identified as strongholds for bull trout, where populations have been documented as stable or increasing (Isaak et al. 2015, High et al. 2008, Meyer et al. 2014, Erhardt and Scarnecchia 2014, Isaak et al. 2022). This is in part due to the high-quality habitat available on the national forest, as well as the life history variation expressed in these populations. Bull trout in streams on the national forest can exhibit three different life history strategies including resident, adfluvial, and fluvial. Resident fish remain in headwater streams for their entire lives, which can provide genetic insurance against downstream catastrophic disturbance events. Adfluvial bull trout on the national forest live in the cold, deep water of Dworshak Reservoir and migrate up the North Fork Clearwater to headwater streams to spawn. Erhardt and Scarnecchia (2014) found that this population had increased in the eight years from 2000 to 2008 and predicted that by 2019 it would likely pass the U.S. Fish and Wildlife Service recovery goal of 5,000 adults. Abundance data for validation of this prediction is still being analyzed. Fluvial bull trout live in large mainstem rivers like the Snake and Clearwater and undergo seasonal migrations to headwater streams to spawn. All of these life history forms can be found together on spawning grounds, and the subsequent genetic exchange adds to population resilience of bull trout on the national forest. Isaak et al. (2015) predicted areas of cold-water refugia that would be the most important factor in bull trout persistence in the northern Rocky Mountains. Isaak (Isaak et al. 2022) recently proposed a strategy to target restoration efforts in these stronghold areas, which comprised from 5 to 21 percent of habitat, but 72 to 89 percent of occupied habitat. Falke et al. (2015) assessed climate change vulnerability of bull trout in the Wenatchee basin in Washington (which, like the national forest, is a fire prone landscape) and found that fuels management and addressing connectivity could mitigate for climate vulnerability of bull trout in that landscape. Most of the headwater stream reaches on the national forest are found in Management Area 1 (roadless, wilderness, etc.) and the only management that would be occurring there is allowing wildland fire to burn.

Spring and Summer Chinook

Crozier et al. (2021) modeled life cycle climate effects on the Snake River Spring and Summer evolutionary significant unit (ESU) and predicted up to an 18 percent decline in survival during the freshwater stage by 2060. This prediction is similar to that of Tonina et al. (2022), who predicted a 20 percent reduction in rearing habitat for spring Chinook in the Salmon River basin and up to a 23 percent reduction in spawning habitat by 2040. Because spring Chinook are anadromous and spend most of their life in marine environments, climate effects on marine survival cannot be overlooked and help to add perspective to discussions of freshwater effects. National Oceanic and Atmospheric Administration Fisheries' life cycle model Crozier et al. (2021) predicted a much larger decline (83 to 90 percent) during the marine stage by 2060, primarily driven by a rise is sea surface temperature. Although most of the projected population effects of climate on this spring Chinook ESU will occur in the marine environment, there are few mitigation options available there. As a result, freshwater mitigation efforts such as protecting and restoring stream habitat may become more important to population resilience. This ESU of spring Chinook scored very high in vulnerability, but high in adaptive capacity during the recent climate change vulnerability assessment (Crozier et al. 2019).

Fall Chinook

Fall Chinook life history takes place largely downstream of the Nez Perce-Clearwater boundary, however climate effects that occur on the national forest will likely impact those downstream areas. Connor et al. (2019) modeled climatic effects on the Snake River fall Chinook ESU and noted that indirect effects of flow and temperature on migration and rearing would likely reduce reproductive success by up to 30 percent but noted that hypolimnetic water releases from storage reservoirs could become increasingly important in temperature mitigation. In particular, they predicted that releases of cold water from Dworshak Dam into the Clearwater River could concentrate reproduction success in that area and perhaps mitigate for losses in other river sections where cold water releases are not available. This ESU of fall Chinook scored high in both vulnerability and adaptive capacity during the recent climate change vulnerability assessment (Crozier et al. 2019).

Steelhead

Steelhead, like spring Chinook, utilize streams on the Nez Perce-Clearwater for extended (multi-year) juvenile rearing, as well as adult migration and spawning. Steelhead, unlike spring Chinook, are very widely distributed throughout the national forest, from mainstem rivers to headwater streams. They exhibit a wide range of life history variation, from resident fish that never leave headwaters, to fish that rear in freshwater for 1 to 5 years (most commonly 2 to 3) before exhibiting anadromy (Copeland et al. 2017). The prolonged and diverse use of habitat on the national forest, combined with a high degree of adaptability, makes it difficult to predict climate effects on steelhead. Steelhead that occur on the national forest are classified as summer steelhead, meaning that adults migrate upstream to spawn primarily in August and September. Many of these fish hold over fall and winter in larger mainstem rivers and reservoirs in the system before completing migration to natal areas during winter and spring and spawning in April and May (National Oceanic and Atmospheric Administration, 2021). Even before impoundment of the Snake and Columbia rivers, river reaches in the adult migration corridor commonly exceeded critical temperature thresholds (68° F) in summer (National Oceanic and Atmospheric Administration 2017), which may have created thermal barriers to migrating adults during summer months. In addition, base flows in some stream reaches drop to levels creating passage barriers that can impede adult migration. Much of the steelhead spawning and rearing habitat on the national forest is prone to wildfire during the late summer months. Adult steelhead behaviorally mitigate for warm migration temperatures by use of cold water refugia during summer for extended periods (Hess et al. 2016, Keefer et al. 2018). Strategies such as holding in mainstem habitats or other pockets of refugia until stream temperatures drop and flows increase and potential fires are extinguished by seasonal weather patterns, or straying to other suitable spawning locales, are adaptations developed over millennia and provide an evolutionary advantage in a landscape historically characterized and shaped by frequent natural disturbance. A wide range of phenotypic and behavioral plasticity, and a wider thermal tolerance (Sloat and Osterback 2013, Spina 2007) and migration ability has enabled steelhead to persist over a much larger geographical area than Chinook on the national forest. (Wade et al. 2012) conducted one of the first landscape scale climate vulnerability assessments on steelhead in the Pacific Northwest (PNW). They concluded that the most severe climatic effects would be seen in steelhead at the southern extant of their range, with a subsequent range shift northward, and concluded maintaining connectivity across the entire PNW would provide more of a buffer to climate effects than local-scale habitat restoration. The Endangered Species Act (ESA) recovery plan notes the current and potential future importance of seasonal cold hypolimnetic releases from hydropower projects in both the Snake and Clearwater basins, which maintain connectivity during summer months and may partially mitigate for more frequent temperature exceedance that is likely to occur under climate change (National Oceanic and Atmospheric Administration 2017). There is a high degree of uncertainty involved in assessment of net effects to a highly adaptable fish like steelhead. Using optimal temperature modeling, Zhang et al. (2019) predicted that steelhead survival rates in the Snake River basin are expected to increase by more than 10 percent by 2080 due to mean river temperature increasing into the optimal range for steelhead growth. Wade et al. (2003) predicted that population groups on the national forest would be less vulnerable to climate impacts than population groups within the distinct population segment (DPS) at lower elevations. This DPS scored high in vulnerability and moderate in adaptive capacity during the recent climate change vulnerability assessment (Crozier et al. 2019).

Sockeye

Although most of the life history of Snake River sockeye takes place outside of the Nez Perce-Clearwater boundaries, a portion of the migration corridor for adults and juveniles (mainstem Salmon River) forms the southern border of the national forest. Sockeye are critically endangered and particularly vulnerable to extinction based on their life history. Adult sockeye migrate up to natal areas during the hottest part of the summer, and lower snowpack could exacerbate in-river temperatures. In 2015, a large portion of the adult run died in the Columbia River due to record high temperatures and low flows in the basin encountered during their spawning migration. Crozier et al. (2020) projected that changes in temperature and flow that affect sockeye would be greatest in the free-flowing mainstem Salmon River. They predicted an 80 percent decrease in adults surviving upstream migration by the year 2040 under current climate predictions. There is likely little that can be done within the boundaries of the national forest to mitigate for this. The Endangered Species Act Recovery Plan (National Oceanic and Atmospheric Administration 2015) identifies coordinated management actions that need to occur and the agencies responsible for implementation, (Table 7.1, National Oceanic and Atmospheric Administration 2015), but all of the identified actions take place outside the Nez Perce-Clearwater National Forest boundaries. If future temperature and flow regimes approach what was observed in 2015, continued failure of spawning migrations could be expected unless there is "coordinated management throughout the migration corridor" (Crozier et al. 2020). An example of the type of mitigation action needed was cited by Crozier et al. (Crozier et al. 2020): in 2015, some fish were saved by Idaho Department of Fish and Game transporting them via truck from Lower Granite Dam to the hatchery, however transportation from Bonneville Dam would have likely been more effective because many fish died before reaching Lower Granite. This evolutionary significant unit scored very high in vulnerability and low in adaptive capacity during the recent climate change vulnerability assessment (Crozier et al. 2019).

Overall

The revised forest plan establishes plan components that continue, and in some cases exceed, the protection afforded by PACFISH and INFISH (Appendix E). These plan components are also intended to maintain physical or biological features (Appendix F). It is the intent of these plan components to continue to protect and enhance freshwater spawning and rearing habitat relating to future activities on the Nez Perce-Clearwater. In addition, the philosophical basis for management changes under the new plan, as activities on the national forest are intended to consider the natural range of variation (NRV) and move conditions at the landscape scale toward a set of desired conditions within the scope of NRV. Bisson et al. (2009) noted that restorative actions would be more "likely to foster salmon resilience if they consider processes that generate and maintain natural variability in freshwater." In the face of climate challenges, cultivating population resilience will likely play a larger role in the continued persistence of threatened fish species on the national forest.

The Northern Rockies Adaptation Partnership (NRAP) is a science-management partnership consisting of 15 national forests in the Northern Region of the U.S. Forest Service, three National Parks, U.S. Forest Service Rocky Mountain Research Stations, University of Washington, and numerous stakeholders. They published a volume (Halofsky and Peterson 2018) identifying climate change issues relevant to resource management in the northern Rocky Mountains and discussing solutions that minimize negative effects of climate change and facilitate transition of diverse ecosystems to a warmer climate. They included recommendations and adaptation options for a wide range of resources on the Nez Perce-Clearwater, including water resources and infrastructure, fisheries, forest vegetation, rangeland vegetation, wildlife, and recreation. It is intended that this document will guide and assist mitigation for climate effects at the project level, and potential climate adaptation strategies developed through NRAP have been incorporated into the development of plan components.

The revised plan addresses climate change impacts at the resource level through resource specific plan components, and at the national forest level by coordination of plan components to achieve desired conditions. There are individual resource plan components in the revised forest plan that will help to mitigate potential climate change effects on fish. For example, one of these is the creation of the Conservation Watershed Network, which, among other things, identifies areas of cold water refugia that are likely to persist into the future. This enables restoration actions to be focused on areas likely to be increasingly important to cold water fishes in the future. The Conservation Watershed Network (CWN) also focuses on maintaining and improving connectivity of watersheds, allowing for natural selection of advantageous adaptations among listed fishes, thus maximizing potential for genetic variability. In addition to resource specific examples, the revised plan in its entirety is designed to promote restoration of natural landscapes and natural processes, and plan components that address these issues will cultivate population resilience. For example, plan components from multiple resource areas will affect riparian areas, but all are designed to be beneficial by facilitating natural processes that slow evaporation, and provide shade and instream cover, and promote proper functioning of riparian areas. These processes contribute to stream health. Because healthy streams are most resilient to disturbance (Pelletier et al. 2020) and better able to adapt to changing climates (Bisson et al 2009), they provide the best opportunity for continued persistence of Endangered Species Act (ESA) listed fishes on the national forest. Restoration strategies can maximize benefits to fish by focusing on maintaining and improving connectivity and restoring and protecting natural stream processes (Bisson, 2009). The full benefit of the philosophy underlying the revised forest plan is that instead of reliance on specific technical strategies to ameliorate local scale effects (Bisson et al. 2009), the focus is now on moving the entire landscape toward desired conditions within the range of natural range of variation (NRV). Instead of relying on individual components that only provide benefit to one resource area, the philosophy underling the components in the revised plan is the same for all resource areas. Virtually all plan components are intended to maintain or increase resiliency to some degree. By focusing on protecting and maintaining natural processes, including streamflow, and allowing for maximum genetic exchange through the maintenance of connectivity, the entire forest plan will foster population resilience in ESA listed fishes and persistence in species of conservation concern. For more information on climate adaptation strategies, how specific plan components in the revised forest plan support the strategies established by the Northern Rockies Adaptation Partnership, and how these strategies will provide mitigation of potential climate effects on fish and aquatic organisms present on the national forest, see Appendix G.

All forest management activities that occur on the national forest are subject to Forest Service best management practices (BMPs). A detailed discussion of these is provided in the Final Environmental Impact Statement, Appendix K.

The use of an adaptive strategy that uses tools applying climate adaptation strategies, such as plan components, technical guidance found in documents like Halofsky and Peterson (Halofsky, Peterson, et al. 2018a, b), and Forest Service BMPs (Edwards et al. 2016)will enable the Forest Service to address the future challenges associated with climate change as they develop, with the flexibility needed to stay relevant in the face of this developing threat.

Effects to Resource from Other Resources

The following discussion focuses on effects to aquatic ecosystems and fisheries presented by the management of other resources areas. For each resource, the general effects of plan components that may contribute to or mitigate effects or maintain general conditions to the benefit of aquatic ecosystems and fisheries or habitats are presented. While effects are reviewed, most individual plan components are not cited as the effects are small or indirect and there are too many to list. Plan components from within a resource area that more directly apply to aquatic ecosystems and fisheries or habitat are specifically listed and discussed.

This section examines these effects from several perspectives, including potential effects to aquatic ecosystems from other relevant resource area objectives in the revised plan, continued expected effects under the No Action Alternative (continuing with the direction of the PACFISH and INFISH Biological Opinion[PIBO]), as well as an analysis of how the revised forest plan components in the action alternatives are designed to carry forward PIBO direction for applicable resource areas.

Effects of Other Resource Objectives and Plan Components on Resource

Terrestrial Ecosystems

The objectives for terrestrial ecosystems in the action alternatives were designed to restore various amounts of land in different vegetation types every five years. The rationale for this acknowledges that because of several factors, there is a lack of diversity in terrestrial ecosystems on the Nez Perce-Clearwater. These objectives set targets for restoration of the various habitat types found on the national forest. Restoration of these forest habitat types will be accomplished using various treatments including fire, timber harvest, and vegetation management. This category includes plan components for several different resource types, including cave and karst features, forestlands, carbon storage and climate change, meadows, grasslands and shrublands, fire management, invasive species, and soils resources. The primary impacts to aquatic ecosystems and fisheries are a result of the treatments used to accomplish these objectives. A more detailed discussion of these potential treatments is found below in individual sections concerning relevant resource areas such as infrastructure and timber harvest, but it is expected that the increase in diversity among habitat types, as well as the movement of terrestrial ecosystems closer to the historic natural range of variability that will result from these objectives will be beneficial in the long run for fisheries and aquatic ecosystems. Any temporary adverse effects of projects are expected to be of short duration and scope and will be outweighed by long term beneficial effects as terrestrial ecosystems become more diverse and natural structure and function is restored across the landscape.

Aquatic Ecosystems

The threats to aquatic ecosystems and fisheries include changes to hydrologic function and nutrient alterations. Mechanical vegetation treatments, off-road vehicles, roads and trails, livestock grazing, and high severity wildfires are some of the actions that affect the hydrologic regimes or nutrient inputs. The action alternatives include desired conditions that would specifically support aquatic ecosystems. The revised plan components have additional protection measures and an increased emphasis on the restoration and maintenance of riparian and aquatic resources.

As a result of these plan components, aquatic habitats are expected to be maintained and continue supporting aquatic species that occur in these habitats. The revised plan is more explicit on aquatic ecosystems protections, connectivity in riparian habitats, and groundwater-dependent systems, in addition to following state guidelines and best management practices in the previous plans.

These plan components are expected to contribute to stable populations for all aquatic species by preserving required habitat characteristics for these species. Habitat quality would be maintained or improved for all at-risk aquatic species.

Specific plan components that more directly benefit fish in wetland, riparian, and meadow habitats include FW-DC-WTR-02, which contributes to habitat connectivity that aids potential fish dispersal for aquatic species. FW-DC-WTR-07 contributes to instream flows sufficient to sustain riparian, aquatic, and wetland habitats. FW-DC-WTR-08 seeks to maintain groundwater dependent ecosystems, including fens, wetlands, seeps, springs, and riparian habitats, which are all habitats that support aquatic species. FW-GDL-ARINF-08 states that wetlands and seasonally wet meadows should be avoided when developing roads and landings and drainage features should maintain wetland functions and characteristics.

For a more in-depth discussion of how aquatic ecosystem plan components affect aquatic ecosystems and fisheries, see the section entitled Comparison of No Action Alternative vs Action Alternatives.

Wildlife

Several of the objectives relating to wildlife direction complement the aquatic ecosystem and fisheries needs by describing a desired condition to manage vegetation to approximate natural succession and disturbance processes and provide a mosaic of habitat conditions through time. These components would generally contribute to the maintenance of diverse habitats for aquatic species. Many National Forest System lands plan components contribute to these overall desired vegetative conditions as well.

Multiple use wildlife objective MA2-OBJ-WLMU-01 could potentially impact aquatic species, as it is designed to include using vegetation treatments and fire to improve elk habitat in Management Area (MA) 2, however much of MA2 is in Idaho Roadless Areas, and as such, impacts from vegetation treatment are expected to be less than if they occurred in more heavily roaded areas that are open to motorized use. Objective MA3-OBJ-WLMU-01 is designed to improve elk habitat use on 19,000 acres in five years. This activity could potentially affect aquatic species if it occurs in riparian areas or close to roads. However, this objective is designed to focus treatments on areas that are more than one-half mile from open motorized roads, which will lessen effects on aquatic ecosystems and fisheries. In addition, there are specific aquatic plan components that are designed to provide additional protection from activities occurring in riparian areas.

FW-GL-GL-01, FW-DC-WL-01, and FW-DC-WL-02 encourages cooperation and collaboration across multiple agencies to work on a variety of planning and management tasks to work toward recovery of federally listed species. While this component is geared mainly to wildlife, the benefits extend to all at-risk listed species. MA-GDL-WL-05 is designed to maintain large areas of unfragmented habitat, and restricts motorized trail use in Idaho Roadless Areas, which would provide benefits to aquatic species. Similarly, under the multiple-uses wildlife plan components, MA2-DC-WLMU-02 is designed to provide areas over 5,000 acres without public motorized access. This will be beneficial to aquatic ecosystems and fisheries by maintaining habitat in these areas.

Air Quality

Air quality can impact aquatic ecosystems and fisheries on the Nez Perce-Clearwater primarily through smoke and ash entering streams, thus altering water chemistry. Plan components FW-GL-AIR-01 and FW-GL-AIR-02 are designed to promote the coordination with partners to reduce air quality impacts prior to planned ignition activities and to cooperate with partners to meet air quality standards.

Tribal Trust

Tribal trust resource plan components are not expected to have negative effects on aquatic ecosystem and fisheries because any activities falling under this resource area are directed by standard FW-STD-TT-01, which is designed to require consideration of impacts, and long-term benefit to treaty rights and treaty-reserved resources. FW-OBJ-TT-01 is designed to restore 1,000 acres of forest in a manner that promotes huckleberry abundance. Huckleberry occurs on upland slopes, so this restoration will not likely affect riparian areas or streams. FW-OBJ-TT-02 is designed to increase wet meadow botanical species that are important to the tribe. Properly functioning wet meadows are important to aquatic ecosystems because they have potential hydraulic capacity to retain water and release it slowly, thus subsidizing stream flow during low flow periods. To increase wet meadow associated species such as camas, the requisite hydrologic capacity will also likely benefit stream flow.

Cultural Resources

This resource area is not expected to have effects on aquatic ecosystems and fisheries.

Municipal Watersheds

Municipal watersheds are protected for water sources (FW-DC-MWTR-01), which would also contribute to maintenance of habitat for aquatic ecosystems and fisheries.

Sustainable Recreation

Motorized and mechanical means of transport impact aquatic ecosystems and fisheries within road prisms and road maintenance activities can affect habitat in these areas. Vehicles that travel on or off-road can disturb and compress soil and generate sediment that can impact aquatic ecosystems and fisheries along designated travel routes and roads open to motorized use. In addition, motorized routes are primary vectors for aquatic invasive species.

Recreation impacts can include trampling, both by hikers and off-road vehicle use. Road building and the development of campgrounds and other facilities used by recreationists also contribute to aquatic and fisheries impacts, as these developments make more areas accessible and concentrated use. Dispersed camping and recreation have similar impacts, which are more difficult to monitor. Parking areas, particularly undesignated areas, pose a similar risk to aquatic species and fisheries especially if they are located near streams.

The recreation objective FW-OBJ-ARREC-01 is designed to mitigate, remove, or relocate two existing dispersed recreation sites from within riparian management zones to outside of riparian management zones every five years. This will help to spread out recreation effects on aquatic ecosystems and fisheries by managing public access at regular intervals. This will spread out effects at different sites on the landscape and should prevent any one site from being over impacted. The decision to apply plan components to achieve this objective will be made at the project level where needed to achieve FW-DC-ARREC-01.

The Aquatic and Riparian Recreation (ARREC) plan components are expected to contribute to the maintenance of aquatic ecosystems and fisheries on the Nez Perce-Clearwater by including protections associated with recreation opportunities. Most aquatic species are protected from recreational related damages by multiple resource areas plan components as well, reducing risk for species that occur in with these habitats. Wilderness Areas and Wild and Scenic Rivers are still protected under national guidance and would continue regardless of alternative. Under the recreation plan components, aquatic species habitat quality would remain similar between the No Action Alternative and action alternatives, with the most protections coming under Alternative W due to increased recommended wilderness.

Scenery

Objectives from the scenery resource are not expected to have effects on aquatic ecosystems and fisheries.

Public Information and Education

Public information and education plan components could benefit aquatic ecosystems and fisheries by connecting people to their environment and to the natural and cultural history of the area. It will do this with a combination of relevant and timely public information, creative interpretation, and stimulating education help the Nez Perce-Clearwater communicate with the public and enable visitors to be involved in the activities, actions, and expectations for activities on Nez Perce-Clearwater lands. These connections will provide opportunities for the development of strong stewardship ethics and appreciation for the natural and cultural history across these landscapes. As a larger proportion of the public that is connected and involved in natural resource management, more people will feel invested and act as instruments of sound public policy. In particular, the guidelines found in FW-GL-ED-1-5 are designed to foster partnerships and stewardship in appreciating and protecting natural resources. This will help to achieve desired condition FW-DC-ED-1-3.

Infrastructure

Infrastructure objectives such as those described in FW-OBJ-INF-01, FW-OBJ-INF-02, FW-OBJ-INF-03, can have potential impacts on aquatic ecosystems and fisheries on the Nez Perce-Clearwater. In general, increased ground disturbance associated with creation, maintenance, and decommissioning of roads corresponds with the potential for increased sediment to enter streams, and roads and trails can be vectors for nonindigenous species.

The primary concern with road and log haul activities in regard to aquatic ecosystems and fisheries is the generation of fine sediment, and the potential for it to enter streams. Although sediment production and transport are natural ecosystem and stream processes that occurs on the national forest, the timing and type of sediment can create problems if it enters streams. Historically and today, streams on the national forest transport vast amounts of sediment during spring snowmelt and other disturbance events. This sediment transport is vital to proper stream ecosystem function, and is important in several key ways including aquatic nutrient transport and the creation of rearing habitat for Endangered Species Act (ESA) listed salmonids. However, the wrong kind of sediment at the wrong time of year can cause deleterious impacts to spawning habitat. Snowmelt and large precipitation events that occur in spring can cause large amounts of overland and underground flow to streams. As stream levels rise, the hydraulic capacity of the stream to move sediment increases greatly, thus transporting sediment downstream, carrying some out of the plan area, and depositing some in natural beach areas along larger rivers in the plan area. These natural sand beaches are important rearing areas for some out-migrating juvenile salmonids. However, large input of fine sediment throughout the year, and especially during lower flow seasons, can cause sediment to collect and fill interstitial spaces in spawning gravels, reducing and degrading habitat for fish and aquatic species. Over time, this collection of sediment can lead to armoring, thus making it difficult for future high-water events to remove accumulated sediment. Thus, road construction and associated timber transportation can affect aquatic systems if they create fine sediment that enters streams during the wrong time of year, when water flow is not sufficient to relocate the sediment to natural locations (beaches estuary, etc.). Some aquatic species that rely on fine substrates for part of their life history, such as juvenile lamprey, or Western pearlshell mussel could benefit from some fine sediment accumulation.

Although there is potential for negative effects from infrastructure plan components, there is also potential for mitigation of negative effects, as well as positive outcomes. For example, the desired condition FW-DC-INF-02 is designed to direct that roads not needed are absent from the landscape, which implies that the road network will not be maintained above the minimum needed for administrative and public use. Maintaining a minimum road network should benefit aquatic species by limiting road effects on their habitats. In addition, FW-OBJ-INF-01 is designed to provide direction that priorities will include reducing effects on desired aquatic and riparian conditions from chronic sediment delivery of potential future road prism failures, which will provide protection from these potential threats. In addition, there is an entire suite of Aquatics and Riparian Infrastructure

(ARINF) plan components (7 standards and 11 guidelines) that are specifically designed to create progress toward desired condition FW-DC-ARINF-01 that is designed to describe a transportation system that has minimal impacts on aquatic and riparian conditions through reduced hydrologic connectivity, lower sediment delivery, reduced floodplain impacts, and improved aquatic organism passage in areas where infrastructure affects these features.

Land Ownership

The national forest is expected to continue to own federal land and survey, mark, and maintain boundaries of that land. It also authorizes use of National Forest System lands by private individuals and corporations for a variety of uses, such as roads, utility corridors, communication sites, and other private or commercial uses that cannot be accommodated on private lands. These desired conditions are described in FW-DC-LND-(01-05). These plan components are not expected to have effects because there is an entire suite of Aquatic and Riparian Land and Special Use plan components (FW-DC-LND (4 standards and 1 guideline) explicitly designed to protect aquatic ecosystems and fisheries from land use actions. In addition, any government agency would be required to undertake Section 7 consultation for any actions that might affect listed species.

Ecosystem Services

Ecosystem services desired condition FW-DC-ES-01 describes the provision of benefits including clean water, clean air, wood products, forage, hunting, fishing, trapping, fish, cultural values, subsistence food gathering, spiritual and inspirational value, scenery, recreation, and flood control, soil stabilization. It is expected that plan components for this resource areas could have potential effects on aquatic ecosystems and fisheries, primarily through guideline FW-GDL-ES-01, which is designed to continue to provide motorized access to the public, and specifies that if a route is identified as adversely affecting aquatic values, re-routing and route improvement should be considered prior to closure, and that if a route does need to be closed, and alternate should be provided. This could affect aquatic resources if in practice it restricts the ability to close problematic roads. Alternately, it could benefit aquatic resources if problem roads are improved, re-routed, or closed. If old roads were decommissioned, or if new roads were built to maintain access, they would be subject to Aquatics and Riparian Infrastructure (ARINF) plan components, best management practices (BMPs), and would be required to undergo Endangered Species Act (ESA) consultation for effects to listed species at the project level.

Timber Production and Vegetation Management

Timber Production

Timber harvest is most likely to occur on lands identified as suitable for timber production. Harvest increases some threats to aquatic ecosystems and fisheries but also can create a mosaic pattern on the landscape and promote early successional stands with some treatments, such as regeneration harvest. Typically, aquatic ecosystems and fisheries would receive site-specific protection as a result of federal ESA consultation (Forest Service Manual 2670) and negative effects would be minimized for ESA listed species. However, ESA listing consultation requirements would cover virtually all of the streams where timber harvest is likely to occur. This would continue to occur with the proposed plan components following project-level evaluation procedures and continued required ESA consultation.

All alternatives have varying amounts of land suitable for timber production, but the impact of timber plan components on aquatic ecosystems and fisheries is consistent between action alternatives. The moist forest habitat guild would be most impacted by timber management, but all habitat guilds can be affected by timber production even if habitats guilds, such as aquatic, subalpine, meadow, rocky or grassland, are not directly harvested for timber. Mechanical activities include vegetation management treatments, whether for restoration or to meet timber production objectives. Activities, such as logging, can have impacts on aquatic ecosystems and fisheries through canopy removal, soil disturbance and erosion, and stream sedimentation. In addition, mechanical activities for vegetation treatment may require road building. Roads can increase access to aquatic ecosystems and fisheries and can fragment habitat, thus, providing an avenue for invasive plant species. Reconstruction and maintenance of designated roads can directly or indirectly affect stream habitat by introducing competitive weeds and altering availability of light, nutrients, and moisture.

Timber output targets in the action alternatives range from 8 to 100 million board feet (MMBF) in Alternative Z to 241 to 261 MMBF in Alternative X. The Preferred Alternative sets targets of 190 to 210 MMBF. This represents approximately four times the amount of harvest, and there have been concerns about a commensurate increase in forest roads. As discussed previously, the national forest permanent road system that currently exists on the Nez Perce-Clearwater National Forest was built with an intended capacity of approximately 400 MMBF, and although the increased targets in the Preferred Alternative represent an increase from the No Action Alternative, there is still only about half of the timber volume that the permanent road system is designed for. A significant increase in permanent roads is not likely to occur under the life of the plan. There will, however, likely be an increase in temporary roads. There are several ways that the national forest can limit impacts from temporary roads. First, every road constructed on the national forest, even temporary roads, is engineered. Engineering can incorporate design features and best management practices (BMPs) that have been shown to reduce sediment delivery to streams by 80 percent. In addition, with the increase in timber sale volume, there will also be an increase in timber receipts available for restoration and mitigation. There are also strong ecosystem plan components that protect and preclude activities that retard attainment of desired conditions. These will be accomplished by applying measures such as no new streamside roads, hydrologic disconnecting of roads, and culvert replacement for roads that already exist, a soils guideline that allows use of timber receipts to repair legacy damage in addition to mitigating for current disturbance. There is also direction designed to facilitate working together with partners such as Idaho Department of Fish and Game and the Nez Perce Tribe to achieve restoration. More discussion of potential road and sediment effects are found in the Effects to Resource from Other Resources section under the Infrastructure section.

As a result of plan components and policies, aquatic species and their respective habitats would be considered during vegetation management, and habitats are expected to be maintained and continue supporting aquatic species despite the potential for impacts in areas used for timber production. The revised plan is more explicit regarding resource protections, though similar guidance and policies are applied under the old plans. Habitat quality would remain similar between the No Action Alternative and action alternatives for aquatic species under the timber plan components. Threats would be reduced for aquatic species by the action alternatives plan components because they were designed to clarify previous protections afforded by PACFISH and INFISH Biological Opinion (PIBO) by including additional language.

Several plan components express a desired condition to restore a mosaic of forest vegetation that is closer to the natural range of variation (NRV) for species composition and opening size. As timber management is only permitted in Management Area (MA) 2 and MA3 lands, those are the categories that have plan components relating to timber harvest. Restoring a more natural structure to the national forest in these areas will help to restore function as well, including hydrologic processes such as FW-DC-FOR-03, FW-DC-FOR-06, MA1-DC-FOR-09, MA2-DC-FOR-10, MA3-DC-FOR-10, MA3-DC-FOR-07, and MA3-DC-FOR-12. Specific objectives directing the restoration of forest types that support successional stages that could benefit aquatic species include MA2-OBJ-FOR-01 and MA2-OBJ-FOR-03. Riparian forests, which are important to filtering sediment from overland flow and providing shading, and pool habitat by contributing large woody debris, would be supported by MA2-DC-FOR-10 and MA3-DC -FOR-10, which seeks to maintain old growth (much of which occurs in riparian areas). There are numerous plan components under this resource that will contribute to an array of forest cover types and structure to support general aquatic diversity and stream ecosystem function.

Vegetation Management

Aquatic ecosystems and fisheries are potentially affected by the action alternative's vegetation desired conditions. Broadly, the desired conditions for terrestrial vegetation on the Nez Perce-Clearwater are characterized by improvements in species composition, desirable densities, and general forest health and condition; vigorous non-forested plant communities; and maintaining native biodiversity on the landscape. The desired conditions are consistent with the Forest Service's understanding of the natural range of variation (NRV) and are most likely to be resilient in the future given expected drivers, such as climate change, drought, vegetation succession, wildfire, insects and disease, and the demands of people. Desired conditions for vegetation support native species and habitats within their NRV, including at-risk species.

Ground disturbing activities and changes in site conditions that could impact aquatic species are likely to result from the terrestrial vegetation plan components. The restoration of historical fire regimes and restoration of conditions towards historical range of variation with a range of seral stages for different potential vegetation groups may benefit some aquatic in the long term by restoring structure and ecological function to the national forest.

All of the action alternatives set targets for forest restoration treatments of 53,000 to 64,500 acres per year. This is an increase from the No Action Alternative, which sets a target of 40,000 acres per year.

These revised vegetation plan components are expected to maintain and continue supporting aquatic ecosystems and fisheries on the Nez Perce-Clearwater. Generally, habitat quality would be maintained or improved for aquatic species under the plan components in the action alternatives. Threats would remain similar for aquatic species in regard to vegetation plan components. While some occurrences could be impacted, generally activities would maintain a more diverse and natural range of vegetative habitats which would benefit aquatic species.

Plan components that maintain older forests are beneficial to the persistence of aquatic species in riparian areas. Contributing components include MA3-STD-FOR-01, MA3-GDL-FOR-02, MA3-GDL-FOR-03, MA3-GDL-FOR-04, and MA3-DC-FOR-10. Desired conditions that support aquatic, meadow habitats that support aquatic species include FW-DC-GS-01-08.

Fire

Under all alternatives, fire would be used as a tool to accomplish management goals and objectives. The objectives for fuel reduction are usually complementary to the other desired vegetation conditions, including those beneficial to aquatic ecosystems and fisheries especially as related to forest resiliency. There are several factors that are important to consider with regard to aquatic ecosystems and fisheries. One factor that is important to aquatic ecosystems is the risk of high severity wildfire resulting from high fuel loads. The current condition is an overall high risk of high severity burns across much of the Nez Perce-Clearwater due to high fuels load, which has resulted from past fire suppression and the outbreak of bark beetle infestations. Without some prescribed fire introduced to mitigate the threat of high severity fire, aquatic species populations are susceptible to being eliminated or reduced in areas on the national forest through the direct threat of fire, or high sediment loads following high severity fires. Many species tolerate, and in fact require, frequent low severity fire to maintain populations on the landscape. Stand replacing fires have the potential to directly kill aquatic species, or to indirectly kill or impact them through habitat impacts, such as the reduction or elimination spawning areas. This can make re-establishment difficult or even impossible for many years (Leonard et al. 2017 (Leonard et al. 2017)).

Another factor to consider is that some riparian or aquatic species benefit from regular small intensity fire to maintain a mosaic patten of openings that allow some light into the stream and can increase productivity. In addition, low intensity fire can help to create large woody debris in streams. Flitcroft et al. (2016) found that fire increased habitat quality for spring Chinook. Anadromous fish, because they are well adapted to natural disturbance regimes, highly migratory, and utilize different habitats over large scales, often benefit from habitat enhancing or maintenance effects of low intensity fire (Reeves et al 1995). The reduction of fire on the landscape has generally reduced the amount of available habitat for such species. In general, most aquatic species would benefit from the restoration to more historical fire regimes. There are also potential impacts to aquatic ecosystems and fisheries associated with wildfire suppression activities, such as fire line construction and other mechanical activities, reforestation following fire, and the increased potential for the spread of noxious weeds.

Aquatic habitats can have various reactions to fire. As a result of these plan components, all aquatic habitats are generally expected to be maintained and continue supporting aquatic species, including the species that are currently on the sensitive species list but that would not be specifically protected as a species of conservation concern once the new plan is implemented. Analysis prior to project implementation allows for appropriate mitigation to be developed when necessary to account for aquatic species.

Plan components MA2-OBJ-FOR-08 and MA3-OBJ-FOR-08 seek to restore cold forests through fire. This would benefit habitat conditions favoring cold water species such as bull trout, especially resident populations in headwater streams. Desired conditions that seek to support ecosystem function and meet desired conditions of other resources through a range of burn conditions, fire intensities, and fuel conditions of more historic fire regimes include FW-DC-FIRE-04, FW-DC-FIRE-05, and FW-DC-FIRE-06. Also, the goal of building understanding of fire's role in sustaining fire adapted ecosystems, as stated in FW-GL-FIRE-04, is important to anadromous fish habitat where fire is a component. Fire guidelines FW-GDL-FIRE-02 and FW-GDL-FIRE-03 are designed to decrease the expansion of invasive weeds and are important for all aquatic species.

Energy and Minerals

Locatable mineral entry is a non-discretionary Forest Service action; National Forest System lands are open to locatable mineral entry unless withdrawn from mineral entry.

Development of energy and mineral resources has the potential to adversely impact aquatic ecosystems and fisheries through all phases of development. Impacts could include mortality to individual aquatic species, or entire populations, as well as habitat loss and fragmentation if mineral resources are occurring in or near streams. Under plan components, aquatic habitat quality would remain similar between the No Action Alternative and action alternatives. Threats would be reduced for aquatic species by the action alternatives plan components including FW-GDL-AREM-01, which calls for avoidance of wetlands and riparian areas in mineral operations and requires the use of native revegetation efforts as part of operations.

A second set of plan components related to energy and minerals regarding aquatic ecosystems and fisheries is found in the Aquatic Ecosystems section. Specifically, FW-STD-AREM-01 requires mineral operations to have a bonded reclamation plan that avoids adverse effects to fish. In addition, FW-STD-AREM-03 requires mineral activities on National Forest System lands to avoid or minimize adverse effects to aquatic threatened or endangered species and populations or their designated critical habitat.

Livestock Grazing

Aquatic ecosystems and fisheries have the potential to be impacted by livestock, which when grazed improperly can cause hydrologic changes, trampling of fish redds, habitat degradation through bank trampling, and soil impacts. Aquatic ecosystems and fisheries are most likely impacted by livestock grazing in riparian habitats. Aquatic species would be protected by Forest Service manual guidelines and plan components during project level planning to prevent or mitigate negative impacts.

As a result of these plan components, the affected habitats are expected to be maintained and to continue supporting aquatic species in livestock allotments. There would be opportunities in the future to restore habitats that have become degraded over time. The language in the revised plan is more explicit than the other plans, but management direction to preserve habitat quality is generally similar. Habitat quality would improve with the action alternatives for aquatic species in aquatic ecosystems due to grazing components to improve or maintain quality habitat.

FW-GDL-GRZ-01 seeks to reduce impacts resulting from livestock use to benefit riparian areas, meadows, and other habitats that are important to Endangered Species Act listed fishes and species of conservation concern. FW-GDL-GRZ-03 directs that utilization occurs at levels that will maintain vegetative vigor and community health and planning considers the condition, timing, and use of the resource along with other values of the area. This is important to maintain overall health of riparian habitats and to prevent overall habitat degradation which harms aquatic species.

The guidelines FW-GDL-GRZ-01, FW-GDL-GRZ-02, and FW-GDL-GRZ-03 direct the mitigation or relocation of facilities to avoid impacts to riparian management zones. Such activity would benefit the aquatic species that depend on riparian areas.

Special Forest and Botanical Products

The special forest and botanical products resource is not expected to impact aquatic ecosystems and fisheries because these types of activities (for example, huckleberry picking and firewood gathering) are not expected to occur at a scale that could impact aquatic ecosystems and fisheries. If effects did occur, plan components FW-DC-SFP-01 and FW-DC-SFP-02 are designed to describe a desired condition that includes harvest that is sustainable and protects resources.

Land Allocation and Designated Areas

The alternatives vary in quantity and location of management areas. Designated wilderness areas, wild and scenic rivers, historic sites, and research natural areas do not vary in location or area. The alternatives vary in the number of inventoried roadless areas that are retained or recommended for wilderness. Management Area 3 changes slightly across the alternatives but is largely consistent.

Alternative W offers the most area protected in areas that would see the fewest management activities. These more undeveloped and protected areas would generally protect aquatic ecosystems and fisheries from ground disturbing threats and development, and these areas would be managed allowing natural fire regimes to contribute to a mosaic of different seral stages and diversity of habitats as much as possible. An increase in these protected areas decreases threats to aquatic ecosystems and fisheries overall from ground disturbing activities, such as vegetation projects, some motorized and mechanized access, and weed spread vectors, while promoting a naturally managed system that has the potential to improve the mosaic pattern on the landscape. However, cold water species like bull trout could see less protection in protected areas if there are large and extensive wildfires that reduce stream canopy and create risk of debris torrents in wilderness. Management Area 3 allocated ground is subjected to more vegetation management, but the needs of aquatic ecosystems and fisheries can be incorporated in planning efforts to protect them when necessary. See the Differences in Plan Direction and Land Allocation section for more details on the management differences between these land allocations.

All action alternatives would have the ability to achieve desired vegetation conditions within inventoried roadless areas using vegetation treatments. All have Land Management Plan direction that allows restoration activities to occur as long as the laws and policies governing such activities are met. Anticipated vegetation treatment activities would often be associated with the national forest restoration and salvage from existing roads, prescribed fire, and restoration of higher elevation whitebark pine forest communities. There may be other treatments occurring to achieve restoration objectives outlined in the plan components.

Several wilderness components direct management that maintains wilderness characteristics which exclude many activities that are potentially harmful to aquatic species and fisheries. Similarly designated wild and scenic river components protect the river corridors and the habitats contained from activities that may interfere with the protection and enhancement of the values for which the river was designated. In the case of suitable wild and scenic rivers, vegetation management is only allowed to protect users, maintain habitats for at-risk species, or maintain or enhance values (MA2-GDL-SWSR-09). Roadless areas provide undisturbed habitat for several aquatic species, including Endangered Species Act listed salmonids (MA2-DC-IRA-05) and enable dispersal and genetic exchange through habitat connectivity (MA2-DC-IRA-02). Disturbance from forest products for personal and commercial uses is not authorized in research natural areas (MA1-OBJ-RNA-01).

Research Natural Areas

There are 23 research natural areas (RNA) included in the revised plan. These are areas that are permanently established to maintain natural ecosystems and areas of special ecological significance. The majority of these occur in rivers, streams, lakes, or creeks. Plan components MA2-STD-RNA-01 and MA2-STD-RNA-02 are designed to prevent authorization of collection of forest products for personal or commercial uses and prevent uses that interfere with RNA objectives or purposes. These components will likely provide benefit to aquatic ecosystems and fisheries by preserving some of the unique ecological features found on the Nez Perce-Clearwater.

Geographic Areas

Plan components that concern Geographic Areas, including GA-OBJ-GH-(01-04) and GA-GDL-GH-(01,02), are designed to provide treatment targets for various locations within the geographic areas. The desired conditions that these treatments are intended to move toward are described in GA-DC-GH-01, which states that the areas provide multiple ecosystem services consistent with legislation. In doing so, these areas will be afforded protections afforded by guidelines GA-GDL-GH-01 and GA-GDL-GH-02, which are designed to implement timber harvest in a manner that initiates, supports, or contributes to a trend toward aquatic desired conditions at the HUC12 scale. This will likely benefit aquatic ecosystems and fisheries.

Area in the Lower Salmon River Geographical Area, GA-OBJ-SR-01 is designed to restore 100 acres of mountain quail habitat every five years. Desired condition GA-DC-SR-02 is designed to describe a Ponderosa pine forest where understory characteristics do not facilitate stand replacing fires and are resilient to climate change. These desired conditions will likely benefit aquatic ecosystems and fisheries by preventing severe fires that could impact aquatic species and habitat.

The other two geographic areas, Pilot Knob and the Lolo Trail, are primarily concerned with places that are culturally significant to the Nez Perce Tribe, and as such, plan components associated with these areas are unlikely to affect aquatic ecosystems and fisheries.

Special Areas

Plan components from the special areas resource are not expected to have effects on aquatic ecosystems and fisheries.

Comparison of No Action Alternative (PACFISH/INFISH) vs Action Alternatives (ARCS PLAN COMPONENTS)

Recommended Wilderness

No Action Alternative

The 1987 Forest Plans propose approximately 198,200 acres of recommended wilderness, across both the Nez Perce and Clearwater National Forests. In addition to lands already included in designated wilderness, continuing to manage these acres as recommended wilderness would continue to allow mostly natural processes to dominate riparian function and processes. Exceptions would include suppression of wildfires and some uses that would be non-conforming in an authorized designated area. Such uses that could affect riparian areas include building replacement where buildings are in riparian management zones and possibly continued motorized use on “cherry stem” routes associated with Fish Lake off the North Fork Clearwater and East Meadow Creek.

The No Action Alternative offers the second least amount of recommended wilderness behind Alternative W, which offers none. Natural disturbances such as fire, floods, blowdown, and avalanches would continue to be the main change agents to riparian zones in recommended wilderness areas, to the extent that fires are not suppressed.

Areas of minimal human development such as existing wilderness areas are often sources of high-quality runoff (Brown and Binkley 1994) and the importance of such water will increase as development proceeds. In general, the same can be said of recommended wilderness areas or other areas that are largely roadless and have minimal development. These areas typically provide the highest quality water. Surveys by Haas et al. (1986) and Cordell et al. (2008) indicate that, of the many reasons that citizens value wilderness, protection of water quality consistently receives the highest ranking.

The general high quality of water in wilderness and large, roadless, and undeveloped areas can be attributed to the lack of ground-disturbing activities, human development, and pollution sources such as roads and timber harvest. However, no studies explicitly compare water quality data from within and outside of designated wilderness lands or similarly managed areas. There is habitat data from PACFISH and INFISH Biological Opinion (PIBO) for managed versus reference streams and much of the data for reference streams are from wilderness areas.

Effects common to all action alternatives

For Alternative W, areas proposed include Bighorn-Weitas, Hoodoo, North Lochsa Slope, Mallard-Larkins, East Meadow Creek, Moose Mountain, Rapid River, North Fork Spruce-White Sands, Sneakfoot Meadows, and Meadow Creek-Upper North Fork. All these areas contain streams with high value to fish, including many reaches included in the 2040 modeled Climate Shield for bull trout occupancy and even more for westslope cutthroat trout. As for the No Action Alternative, managing these areas as recommended wilderness for the life of the plan would continue to allow natural processes to drive riparian process and function. Exceptions would include suppression of fires and some uses that would be non-conforming in an authorized designated area. Such uses exclude building replacement under this alternative, as well as recreational aircraft use. Continued motorized use of cherry stem routes to Fish Lake and into East Meadow Creek would be allowed, potentially offering some level of effects to riparian areas. Natural disturbances such as fire, floods, blowdown, and avalanches would continue to be the main change agents to riparian zones in recommended wilderness areas to the extent that fires are not suppressed.

For Alternative X, zero acres of recommended wilderness are included. While it is not clear what, if any, management actions or land access and development activities would occur, it is assumed some level of management actions would occur beyond those that would if they were included as Recommended Wilderness. It would also be expected that suppression of fires would be emphasized to a greater degree, as would motorized recreation opportunities. Given these assumptions, some level of departure of riparian conditions could occur, although since the Aquatic Ecosystems plan components would apply to this alternative and the other action alternatives, effects would be expected to be similar. For example, desired conditions such as FW-DC-WTR-04 and FW-DC-CWN-02 emphasize riparian and stream conditions within natural ranges. Standards such as FW-STD-WTR-04 and FW-STD-CWN-01 contain specific direction to achieve these desired conditions through restoration actions where desired conditions are not met and maintained where they are.

For Alternatives Y and Z, more acres of recommended wilderness are proposed than in the No Action Alternative, but less than Alternative W. Alternative Y includes Mallard-Larkins, Hoodoo with boundary changes, East Meadow Creek, and Rapid River, and has fewer uses that would be non-conforming in an authorized designated area than Alternative Z. Alternative Z includes West Meadow Creek, Hoodoo, Mallard-Larkins, East Meadow Creek, Rapid River, Meadow Creek-Upper North Fork, North Fork Spruce-White Sands, Sneakfoot Meadows, Rawhide, and Pot Mountain and has more of these uses than Alternative Y.

For the Preferred Alternative, recommended wilderness areas are proposed in 108,276 acres within Hoodoo, 77,139 acres within Mallard-Larkins, and 72,795 acres within both East Meadow Creek and West Meadow Creek. The total recommended wilderness in the Preferred Alternative is 258,210 acres. Administrative and commercial uses would be allowed under the Preferred Alternative.

The relatively high forestwide proportion of riparian areas that are within designated wilderness, Idaho roadless, and recommended wilderness, which are expected to have low to no harvest or other land management activities, would provide a high degree of protection to riparian conditions and associated ecological values, including wildlife and aquatic habitat, under all the action alternatives. Existing and recommended wilderness would generally provide the highest degree of protection because human actions are the most restricted in these areas.

Wild and Scenic River Suitability

Effects common to all (including no action) alternatives

Identifying segments of rivers and streams that are suitable for Wild and Scenic River designation would have no direct effect on aquatic habitat because no actions are associated with suitability; however, differences in suitability between alternatives as discussed in section 1.1.63.5.2.3 would provide a framework for future project level decisions and would affect aquatic habitat if suitability decisions lead to designation. Actual designation of the river or stream as a Wild and Scenic River would be the federal action upon which effects to aquatic habitat would need to be described. This decision would not be included under any of the alternatives, although management of eligible rivers as if they were designated would be considered in project planning. Such consideration would not affect aquatic riparian areas because current direction under the No Action Alternative incorporates PACFISH and INFISH and proposed direction included for the action alternatives includes the Aquatic Ecosystems plan components, which are designed to provide direction equal to or more rigorous than direction in the Wild and Scenic Rivers Act. In addition, there are suitability components for recommended Wild and Scenic Rivers that provide constraints and direction for these areas.

Livestock Grazing

Riparian area grazing management can succeed if it enables control of and variation in duration and timing, periods of grazing and recovery, livestock distribution, and intensity of use (Swanson et al. 2015). Several factors influence the impact on resources and recovery of them, including species of plants present, growing conditions, geomorphic setting, stage of stream channel, time within the cycle of droughts and floods, and time since major disturbance. These factors should be considered when considering duration, period, distribution, and intensity of grazing activities.

On the Nez Perce-Clearwater, there are currently 36 active allotments and nine vacant allotments. Of the 36 active allotments, 612,766 acres are included; there are nine vacant grazing allotments totaling 217,172 acres. On the Nez Perce-Clearwater there are 4,590 head of cattle permitted and 2,304 head of sheep permitted, pending a separate National Environmental Policy Act review. The primary grazing season is June 1 through September 30. The cattle grazing program averages approximately 31,608 head months. Currently, sheep grazing has been discontinued due to the risk of disease transmission to wild bighorn sheep.

No Action Alternative

The No Action Alternative would continue management of the grazing program under direction in the 1987 Forest Plans, as amended by PACFISH and INFISH. Current direction in PACFISH specific to grazing includes four standards and guidelines, three of which are relevant to the Nez Perce-Clearwater. They require modification of grazing practices that retard or prevent attainment of Riparian Management Objectives (RMOs) or are likely to adversely affect listed anadromous fish. They also require that new livestock handling facilities be located outside of riparian habitat conservation areas and that livestock trailing, bedding, watering, salting, loading, and other handling efforts be limited to areas and times where they will not retard or prevent attainment of RMOs.

In addition, project-level consultations have required that livestock are managed to avoid trampling of salmon, steelhead, and bull trout redds, which is generally accomplished through timing restrictions in areas where spawning is known to occur or exclosure fences.

In sensitive areas, such as meadows, fences have been installed to exclude cattle from grazing and trampling banks within riparian zones. The fences, combined with riparian re-vegetation and restoration, have resulted in improved conditions within these meadows. Several meadow systems have improved from excluding cattle through fencing. These meadows include, but are not limited to, McComas Meadow (Meadow Creek – South Fork Clearwater River), upper Mill Creek, American Creek/Buck Meadow, Merton Meadow, North Fork Slate Creek Meadow, and Musselshell Meadow, Deer Gulch Meadow, Goodwin Meadow, lower Swartz Meadow, and McGary Meadow.

When assessed at a broad scale, these measures appear to have resulted in either static stream conditions or improving trends based on PACFISH and INFISH Biological Opinion (PIBO) trend data and range implementation and effectiveness monitoring data, which are collected annually. Specifically, streambank stability is one of the PIBO metrics that show a statistically significant improvement when assessed at the national forest scale. Whether this is due to management of the grazing program since 1995 or not cannot be definitively concluded, but it can be concluded that management of the Nez Perce-Clearwater grazing program under PACFISH and INFISH has not made conditions worse. Streambank angle did not result in a statistically significant change in either direction. In the Lower Salmon and South Fork Clearwater subbasins, which combined support well over 50 percent of the Nez Perce-Clearwater allotments and animal unit months, a statistically significant improvement of the overall index has occurred (U.S. Department of Agriculture 2019a). Again, it is not possible to attribute that improvement to changes in grazing management, but it is evident that the program has not resulted in additional degradation at the national forest or subbasin scale.

When assessed at a broad scale, protective measures appear to have resulted in either static or improving trends in aquatic habitat, based on PIBO trend data and range implementation and effectiveness monitoring data, which are collected annually. These improvements would be expected to reduce indirect and cumulative effects to aquatic species.Finescale adverse effects to riparian management zones (RMZs) from livestock grazing are known to exist, although their extent, severity, and locations are highly variable from year to year. The effects have resulted in local changes to stream morphology, such as an increase in width to depth ratio. Monitoring of allotments over the last decade has shown some streambank alteration and reduction in stubble height, as well as specific areas of streambank instability. Any aquatic species present in these areas could be indirectly or cumulatively affected by effects to riparian and aquatic habitat and could be directly affected by the presence of cows. Given the variability of these effects from year to year, it is difficult to provide any conclusions on the extent and significance of any effects to aquatic species.

Effects common to all action alternatives

The action alternatives do not vary, either in terms of level of grazing activity in each alternative or the aquatic components that address their potential effects. The Aquatic Ecosystems plan components include three standards and three guidelines that address potential effects from grazing. Table 141 displays a crosswalk of standards and guidelines between PACFISH and INFISH and the Land Management Plan. The Land Management Plan components are similarly or more protective for aquatic and riparian resources. Specifically, FW-STD-ARGR-01 and FW-STD-ARGR-02 are very similar to analogous standards in PACFISH, FW-STD-ARGR-03 is new as it addresses potential redd trampling. All three guidelines, FW-GDL-ARGR-01, FW-GDL-ARGR-02, and FW-GDL-ARGR-03, contain additional direction for meeting Aquatic Ecosystems plan component desired conditions, focusing on maintaining water quality.

Table 141. PACFISH/INFISH grazing standards and guidelines crosswalk with Land Management Plan standards and guidelines.

PACFISH/INFISH	Land Management Plan
GM-1. Modify grazing practices (for example, accessibility of riparian areas to livestock, length of grazing season, stocking levels, timing of grazing, etc.) that retard or prevent attainment of Riparian Management Objectives or are likely to adversely affect listed anadromous fish or inland native fish. Suspend grazing if adjusting practices is not effective in meeting	FW-STD-ARGRZ-01. Livestock grazing shall be authorized or reauthorized only when measures are included in the authorization to avoid or mitigate adverse effects to fish and riparian habitat that may result from grazing practices. Where livestock grazing is found to prevent or retard attainment of aquatic and riparian desired conditions, grazing practices shall be

PACFISH/INFISH	Land Management Plan
Riparian Management Objectives and avoiding adverse effects on listed anadromous fish. GM-2. Locate new livestock handling and/or management facilities outside of Riparian Habitat Conservation Areas. For existing livestock handling facilities inside the Riparian Habitat Conservation Areas, assure that facilities do not prevent attainment of Riparian Management Objectives or adversely affect listed anadromous fish. Relocate or close facilities where these objectives cannot be met. GM-3. Limit livestock trailing, bedding, watering, salting, loading, and other handling efforts to those areas and times that would not retard or prevent attainment of Riparian Management Objectives or adversely affect listed anadromous or inland native fish. GM-4. Adjust wild horse and burro management to avoid impacts that prevent attainment of Riparian Management Objectives or adversely affect listed anadromous or inland native fish.	modified by practices such as adjusting accessibility of riparian areas to livestock, length of grazing season, stocking levels, or timing of grazing. FW-STD-ARGRZ-02. Where livestock trailing, bedding, watering, salting, loading, off road vehicle use for managing or gathering livestock, and other related activities in riparian management zones are adversely affecting aquatic resources, annual operating instructions shall include measures to mitigate or relocate to other areas or times. FW-STD-ARGRZ-03. During livestock grazing authorizations, reauthorizations, or updates to annual operating instructions, include measures to prevent trampling of fish redds of federally listed fish species and species of conservation concern. FW-GDL-ARGRZ-01. New grazing authorizations and reauthorizations that contain low gradient channels of a less than 2.5 percent valley slope should require end of season stubble height be at least 10 to 15 centimeters along the greenline, by pasture or grazing unit depending on the Rosgen channel type or stream gradient, to help achieve conditions at site scales that enable attainment and maintenance of desired conditions in these locations. Application of the stubble height numeric value should only be applied when it reflects existing and natural conditions for the specific geo-climactic, hydrologic, and vegetative conditions where it is being applied. Indicator values should be adapted over time based on long-term monitoring and evaluation of conditions and trends. Alternative use and disturbance indicators and values, including those in current Endangered Species Act consultation documents, may be used if they are based on best available science and monitoring data and meet the purpose of this guideline. Long-term monitoring and evaluation should be used to adapt this numeric range and/or the use of other indicators. FW-GDL-ARGRZ-02. To maintain water quality and minimize the sediment that is generated and delivered to watercourses from active livestock trailing, new grazing authorizations and reauthorizations should include measures for livestock trail stream crossings and approaches to be hardened or relocated, where needed, to achieve aquatic desired conditions. FW-GDL-ARGRZ-03. To maintain quality and quantity of water flows to, within, or between groundwater dependent ecosystems, water to new or reconstructed spring developments should be protected from livestock trampling.

When assessed at a broad scale, PACFISH and INFISH Biological Opinion (PIBO) monitoring has shown that the proper implementation of livestock grazing standards leads to less impacts to stream conditions. Effects of the action alternatives are expected to be mostly the same, except that the Preferred Alternative and Alternatives W and X might result in more transient forage since more timber harvest could be harvested and result in additional forage in areas that are currently forested.

This forage would tend to be located away from streams due to limited or no harvest within riparian management zones.

The outcome of grazing as proposed in these alternatives is expected to be the same or similar as the No Action Alternative with improved clarification to address any site-specific adverse effects to riparian condition or where grazing is preventing attainment of aquatic desired conditions. At a broad scale, riparian management zone (RMZ) conditions are expected to be maintained with any current improving trends continuing and, where degraded conditions are documented at specific sites, changes in grazing management as outlined in the Aquatic Ecosystems plan components is expected to result in improved conditions.

The outcome of grazing as proposed in these alternatives is expected to be the same or result in fewer effects to aquatic species as the No Action Alternative, with clarified and more detailed direction to address any site-specific adverse effects to riparian condition, or where grazing is preventing attainment of aquatic desired conditions. The addition of FW-STD-ARGRZ-03 addresses potential trampling of federally listed fish species and species of conservation concern fish redds, as well as FW-GDL-ARGR-03 that addresses source water protection for springs and may collectively result in fewer effects to aquatic species.

At a broad scale, RMZs conditions are expected to be maintained, with any current improving trends continuing, and where degraded conditions are documented at specific sites, changes in grazing management as outlined in the Nez Perce-Clearwater Aquatic Ecosystems plan components is expected to result in improved conditions. Improved riparian and habitat conditions would be expected to conserve and restore aquatic species. Desired conditions FW-DC-WTR-04 and FW-DC-CWN-02 emphasize riparian and stream conditions within natural ranges. Standards, such as FW-STD-WTR-04 and FW-STD-CWN-01, contain specific direction to achieve these desired conditions through restoration actions where desired conditions are not met and maintained where they are.

Timber Harvest and Vegetation Management

Several standards and guidelines in the plan guide and restrict the implementation of timber harvest and other vegetation management activities within RMZs. Refer also to Effects of Forestwide Direction on Riparian Areas above.

No Action Alternative

Effects specific to Riparian Areas and Riparian Management Zones

Table 121 summarizes the acres of past timber harvest within riparian habitat conservation areas by subbasin, nearly all of which occurred prior to 1995 when PACFISH and INFISH amended the 1987 Forest Plans. After 1995, only a very limited amount of timber harvest occurred in riparian habitat conservation areas. This harvest was generally limited to hazard tree removal at recreation sites, removal of trees in the right-of-way of constructed temporary roads where they crossed riparian habitat conservation areas, and sale of trees decked from fireline construction during fire suppression efforts, some of which were from riparian habitat conservation areas.

PACFISH and INFISH would continue to be implemented under the No Action Alternative. While standards and guidelines were written to allow harvest, salvage harvest, and other silvicultural treatments in riparian habitat conservation areas, there is ambiguity about the conditions under which these are appropriate actions. The 1995 and 1998 Biological Opinions for these amendments also apply. In Key or Priority watersheds, completion of a Watershed Analysis is required by these Opinions prior to harvest in riparian habitat conservation areas. Given ambiguity in the PACFISH standards and guidelines and perceptions that watershed analyses are difficult and time-consuming to produce, it is likely avoidance of timber harvest in riparian habitat conservation areas would continue.

Other silvicultural treatments, such as precommercial thinning, planting, prescribed fire, and other non-mechanical treatments, have occurred in specific areas in riparian habitat conservation areas since 1995. Project-level consultations have generally driven avoidance of fire ignition in riparian habitat conservation areas, while allowing fire to back into riparian habitat conservation areas instead.

Considering all indicators collectively, PACFISH and INFISH Biological Opinion (PIBO) monitoring data indicates this level of activity in riparian management zones (RMZs) has resulted in no additional degradation of riparian habitat conservation areas or stream habitat since monitoring began in the late 1990s and facilitated improving conditions forestwide (U.S. Department of Agriculture 2019a). Continuing to manage riparian habitat conservation areas the same or similarly would be expected to support this outcome through the next planning period.

PACFISH and INFISH, as well as direction in the 1987 plans and the litigation settlement on the Clearwater National Forest, would continue to be implemented under the No Action Alternative. As previously discussed, direction for timber harvest and other silvicultural activities appears to have resulted in improving trends in stream conditions in some subbasins but not others. In all cases except the Upper North Fork Clearwater subbasin, degradation is not evident. At the national forest scale with all PIBO data combined, an improving trend is indicated (Table 123). PIBO indicators most contributing to this trend include median substrate D50, large wood in the stream channel, percent undercut banks, and macroinvertebrate diversity.

As previously discussed in the effects section for riparian areas, only a very limited amount of harvest has occurred in RMZs since 1995, although other silvicultural treatments, such as planting and precommercial thinning, have been more widely implemented.

Continued management is expected to maintain these trends, which would be expected to result in improved habitat for aquatic species. Trends in the Upper North Fork Clearwater subbasin need further investigation to fully address the prognosis for areas important for bull trout spawning and early rearing.

Effects common to all action alternatives

The effects of timber harvest and vegetation management from the action alternatives, compared to the No Action Alternative, to aquatic habitat have been previously discussed under the Effects of Forestwide Direction and Effects of Forestwide Direction on Aquatic Habitat sections. In addition, there is discussion in the Effects of Other Resource Objectives and Plan Components on Resource section under Timber production.

The soils section of the Nez Perce-Clearwater plan components is designed to provide protection for soils that would also protect aquatic habitats and values associated with riparian areas.

The Land Management Plan riparian management zone (RMZ) components in Table 142 are designed to be more protective for aquatic and riparian resources than that of the standards and guidelines, in PACFISH and INFISH, likely improving compliance.

Table 142 . PACFISH/INFISH timber standards and guidelines crosswalk with Land Management Plan standards and guidelines

PACFISH/INFISH Standards and Guidelines	Land Management Plan Standards and Guidelines
TM-1 PACFISH: Do not include Riparian Habitat Conservation Areas (RHCAs) in the land base used to determine the Allowable Sale Quantity, but any volume harvested can contribute to the timber sale program. TM-1: Prohibit timber harvest, including fuelwood cutting, in Riparian Habitat Conservation Areas, except as described below. a. Where events such as fire, flooding, volcanic, wind, or insect damage result in degraded riparian conditions, allow salvage and fuelwood cutting only where present and future woody debris needs are met, where cutting would not retard or prevent attainment of other Riparian Management Objectives, and where adverse effects on inland native and listed anadromous fish can be avoided. For watersheds with listed salmon or designated critical habitat or priority watersheds, complete Watershed Analysis prior to salvage cutting in Riparian Habitat Conservation Areas. b. Apply silvicultural practices for Riparian Habitat Conservation Areas to acquire desired vegetation characteristics where needed to attain Riparian Management Objectives. Apply silvicultural practices in a manner that does not retard attainment of Riparian Management Objectives and that avoids adverse effects on listed anadromous and inland native fish.	FW-STD-RMZ-01. Vegetation management shall only occur in riparian management zones from the edges of the active stream channel to within 150 feet within Riparian Management Zone Category 1 and to the edges of the active stream channel to 100 feet within Riparian Management Zone Category 2, 3, and 4 to restore or enhance aquatic and riparian-associated resources. Non-mechanical treatments, for example, hand fuel treatments, prescribed fire, small diameter (for example, sapling, pole) conifer thinning, may be authorized if aquatic and riparian-associated resources are maintained. Timber Harvest in this zone shall leave trees on site or use for aquatic restoration. Vegetation management may occur in the outer Riparian Management Zones to meet desired conditions for fuel loading and silvicultural desired conditions, so long as project activities retain functions of the outer Riparian Management Zone, including sediment filtering, large wood recruitment to streams, and protection of the inner Riparian Management Zone from windthrow. Vegetation management in Riparian Management Zones shall not retard attainment of aquatic and riparian desired conditions. FW-STD-RMZ-04. Fuelwood cutting shall not be authorized within 150 feet of the stream edge. FW-STD-RMZ-07. The Riparian Management Zone definitions in the introduction of section 2.2.2 (Riparian Management Zones) shall be used for all actions and projects. FW-GDL-RMZ-01. New landings, skidding, staging, or decking and machine burn piling should be located outside riparian management zones to minimize effects to riparian and aquatic resources. Where new activities inherently must occur in riparian management zones, locate them so that they do not degrade or retard aquatic and riparian desired conditions. FW-GDL-RMZ-02. To reduce the likelihood of sediment input to streams, avoid new road and landing construction, including temporary roads and mechanical trail construction, in riparian management zones except where: • necessary for stream crossings, or • a road or trail relocation contributes to attainment of aquatic and riparian desired conditions, or • Forest Service authorities are limited by law or regulation (for example, General Mining Act of 1872). Temporary roads should be managed to protect aquatic and riparian desired conditions.

PACFISH/INFISH Standards and Guidelines	Land Management Plan Standards and Guidelines
	FW-GDL-RMZ-03. To prevent damage to stream channels, yarding activities should achieve full suspension over the active channel. FW-GDL-ARINF-01. Construction, reconstruction, and maintenance activities of roads, skid trails, temporary roads, and airstrips, should hydrologically disconnect the drainage system from delivering water, sediment, and pollutants to water bodies to prevent concentrated water from directly entering streams. FW-GDL-ARINF-02. To reduce the risk to aquatic resources when decommissioning roads, making roads impassable, or closing roads for longer than one year, roads should be left in a hydrologically stable condition where road drainage is routed away from water resources and landslide prone areas and towards stable areas of the forest floor to provide filtering and infiltration. FW-GDL-ARINF-03. To reduce the risk of sediment delivery from gully formation or mass wasting when closing travel routes such as roads, skid trails, and temporary roads with physical barriers (for example, berms), drainage features should be left in a condition that will function without any maintenance for the planned duration of the closure. FW-GDL-ARINF-04. To reduce road-related mass wasting and sediment delivery to watercourses, new and relocated roads, including skid trails and temporary roads, and other linear features should not be constructed on lands with high mass wasting potential. FW-GDL-ARINF-05. To maintain free-flowing streams, new, replacement, and reconstructed stream crossing sites, such as culverts, bridges, and other stream crossings, should be constructed to prevent diversion of stream flow out of the channels and down the road in the event the crossing is plugged or has a flow greater than the crossing was designed.
RA-2: Trees may be felled in Riparian Habitat Conservation Areas when they pose a safety risk. Keep felled trees on site when needed to meet woody debris objectives.	FW-STD-RMZ-05. Trees felled for safety shall be retained onsite unless more than what is needed to achieve aquatic and riparian desired conditions. Trees shall be directionally felled towards or into streams, where it is safe and practical to do so. If aquatic and riparian desired conditions for wood are met at the site, surplus wood can be transported to other aquatic and riparian restoration project sites. Exceptions to this standard are allowed in developed recreation and administrative sites where needed to address concerns for human safety or infrastructure and when not practicable to leave on site.

The Nez Perce-Clearwater Aquatic Ecosystems plan components for riparian management zones (RMZs) are designed to provide clarified direction for timber harvest, fuel treatments, and other silvicultural activities in RMZs. These components apply equally to all action alternatives; in other words, they do not vary by alternative. Standards and guidelines are intended to accomplish two broad objectives. First, they clarify the conditions under which harvest of timber in RMZs might be appropriate (FW-STD-RMZ-01). Secondly, they limit activities in RMZs associated with harvest and other silvicultural treatments (FW-STD-RMZ-02, 03, 04, 05, FW-GDL-RMZ-01, 02, 03).

Because RMZs are unsuitable for timber production and the purpose of harvest within the zones is limited to actions that are designed to achieve desired conditions for riparian-associated resources, the amount of harvest within RMZs is expected to be a minor amount compared to overall harvest levels. Timber harvest in the RMZs would be for the purpose of promoting desired conditions that maintain or improve ecosystem integrity and promote resilience of the vegetation, water, fish, wildlife, and soils resources. Timber harvest must also be consistent with desired conditions, standards, guidelines, management areas, and state laws. Completion of a multiscale analysis, in conjunction with the Stream Condition Indicator Assessment, as described in Appendix 4, is intended show under which conditions FW-STD-RMZ-01 is met. In addition, completion of a multiscale analysis, in conjunction with the Stream Condition Indicator Assessment, when ignition of prescribed fire is proposed in RMZs provides the background to support the conclusion that these treatments are needed to improve RMZ conditions and prevent degradation.

The Stream Condition Indicator Assessment, used in conjunction with multiscale analysis, assesses aquatic conditions in relation to desired conditions. Depending on the conditions of the aquatic indicators, potential stream and riparian restoration actions help maintain or improve conditions toward desired conditions. The level of restoration needed would be dependent on the extent of impact to the resource and the condition of the indicator during project development.

Due to the specificity included in FW-STD-RMZ-01, which outlines the conditions under which silvicultural treatments including timber harvest might be appropriate, and FW-GDL-RMZ-01, 02, and 03, which contain specific direction for harvest activities, these alternatives are expected to result in similar or the same outcomes as the No Action Alternative. First, given the stringency of FW-STD-RMZ-01, harvest in RMZs is not expected widespread or result in substantial acres of RMZs harvested. Second, given the components mentioned, current trends in RMZs, as indicated by PACFISH and INFISH Biological Opinion (PIBO) data, are not expected to change either on a forestwide or subbasin scale. Third, these components offer specificity not included in PACFISH and, therefore, remove any ambiguity in project planning. And fourth, changes in the definitions of RMZs could result in improved protection for RMZs. These changes include expansion of Category 4 RMZs widths to 100 feet over the entire Nez Perce-Clearwater, which mostly affects the North Fork Clearwater and Palouse basins, and refinement of the definition of Category 1 RMZs to include intermittent streams supporting fish at any time of the year.

These objectives are intended to facilitate meeting Aquatic Ecosystems plan components desired conditions in degraded watersheds, given projected increases in timber harvest under Alternatives W, X, and Y and the Preferred Alternative.

In addition to information contained in the above-mentioned section, the differences between the action alternatives in terms of their allowable levels of harvest and anticipated acres treated should be considered. The action alternatives vary in terms of projected timber sale quantity and the acres anticipated to be treated in Management Areas 2 and 3, in some cases widely as when Alternative X is compared to Alternative Z. Management Area 3 contains lands most departed from desired conditions in terms of vegetation composition but also contains streams most departed from aquatic desired conditions. It contains watersheds with the highest priorities for restoration to support recovery goals for listed anadromous fish in the Clearwater basin. Some of the aquatic restoration objectives vary by alternative according to the amount of timber harvest and other silvicultural treatments needed to move vegetation conditions towards their desired conditions.

These aquatics objectives are intended to facilitate meeting Aquatic Ecosystems desired conditions in degraded watersheds, given projected increases in timber harvest under Alternatives W, X, and Y and the Preferred Alternative. It is unknown if these objectives are sufficient to achieve aquatic desired conditions over the next 30 years, particularly considering projected increases in timber harvest, but the monitoring plan contains elements to address trends in aquatic habitat.

Therefore, it is expected that implementation of the action alternatives would result in the same or similar outcomes as the No Action Alternative since direction in the Nez Perce-Clearwater Aquatic Ecosystems plan components are designed to build and strengthen on direction in PACFISH and INFISH shown in Table 142; carries forward the principle of upward trend from the 1987 Nez Perce Forest Plan and expands it to watersheds on the Clearwater National Forest; and provides clarification for direction that is ambiguous in the No Action Alternative. It is the goal of the objectives, combined with all standards and guidelines, that improving trends that are evident in some subbasins will be maintained and enhanced and, for those where there is presently no improvement indicated on the Lower Clearwater and Upper North Fork Clearwater, movement towards meeting desired conditions will be initiated.

When FW-STD-WTR-04 and FW-STD-CWN-01 are assessed using the Stream Condition Indicator Assessment and multiscale analysis, respectively, stream and riparian restoration actions result based upon the conditions of the aquatic indicators in relation to desired conditions. Restoration actions would maintain or improve conditions toward desired conditions. The level of restoration needed would be dependent upon the extent of impact to the resource and the condition of the indicator during project development. In any case, degradation of existing conditions is not expected, and any improving trends are expected to be supported and not retarded by all action alternatives.

Minerals Development

Past mineral extraction activities have profoundly altered riparian conditions in many areas on the Nez Perce-Clearwater, most notably in tributaries to the Upper South Fork Clearwater River, Slate Creek, tributaries in the Upper North Fork Clearwater River, Lolo Creek, and the Palouse River. Presently, ongoing and new minerals projects are being evaluated, many of which are located in riparian areas.

No Action Alternative

PACFISH and INFISH contain standards and guidelines that address these activities, as shown in Table 143. In addition, a set of standard best management practices (BMPs) are generally applied to exploration activities, requiring reclamation of disturbed areas, particularly those within riparian management zones (RMZs). Many of these BMPs are similar to the standards and guidelines in PACFISH and INFISH. While mineral exploration activities have occurred in RMZs for decades and, in some cases, resulted in a large amount of disturbance, broad scale degradation is not evident in PACFISH and INFISH Biological Opinion (PIBO) monitoring data, even within the subbasins supporting the most recent mineral activity. It is likely aquatic species present in the vicinity of these activities are affected to some degree, however.

Table 143. PACFISH/INFISH minerals standards and guidelines crosswalk with Land Management Plan standards and guidelines

PACFISH/INFISH	Land Management Plan
MM-1. Avoid adverse effects to listed species and designated critical habitat from mineral operations. Minimize adverse effects to inland native fish species from mineral operations.	FW-STD-AREM-03. Mineral activities on National Forest System lands shall avoid or minimize adverse effects to aquatic threatened or endangered species and populations or their designated critical habitat.
